ABSTRACT

An abstract of the dissertation of Philip Darren Jones for the Doctor of Philosophy in Biology presented February 13, 2009.

Title: Molecular Coevolution of Pacific Northwest Hantaviruses and their host, the Deer Mouse, *Peromyscus maniculatus*

Sin Nombre virus (SNV, family *Bunyaviridae*, genus Hantavirus), hosted by the deer mouse, *Peromyscus maniculatus* (family Cricetidae, Subfamily Neotominae), is the primary etiological agent of *Hantavirus* pulmonary syndrome (HPS) in the western United States. HPS, with known pathogenicity only to humans and for which there is no cure or prophylaxis, affects the epithelium of the lungs by making the capillaries leaky, thereby resulting in bilateral infiltrates, and eventually leading to respiratory failure and death by drowning in approximately 38% of hospitalized patients.

In the Americas, *Peromyscus* has been co–evolving with hantaviruses for approximately 12–20 million years, since the first cricetids crossed Beringia, radiating and differentiating into the Neotominae and Sigmodontinae currently found in the New World. As it stands, the evolutionary relationships of deer mice remains unclear, consequently, so too is the associated viral phylogeny, with twelve named quasispecies in the genus *Hantavirus* presently characterized in North America, and twenty five quasispecies in the Western Hemisphere. Evidence of this opacity is seen in the new species that are regularly being discovered from among these host

conspecifics suggesting that many uncharacterized hantaviruses remain to be described.

To improve our understanding of these co–evolutionary relationships, as well as the epidemiology of HPS, specimens of both host and virus were collected from throughout the Portland, Oregon region, as well as other locations across North America. Analyses of the ND3, ND4, ND4L, and arginine tRNA host mitochondrial genes yielded average genetic divergence estimates of 0.0413 among local (Portland, OR) deer mice relative to specimens from the type locality of the species, in Newfoundland. Phylogenetic analysis also revealed a deep division in the phylogeny of deer mice discriminating the distribution into two distinct clades on either side of the Mississippi River, and suggesting that western deer mice in fact are constituted by a formerly cryptic species distinct from those in Newfoundland and eastern North America. Sequencing and phylogenetic comparison of the Pacific Northwest hantaviral G1/G2 glycoprotein precursor encoding gene showed a large genetic distance ($p=0.143$) from Sin Nombre type specimens from New Mexico, suggesting that the Portland area virus minimally constitutes a new strain.

Chapter 1: Introduction

Epizootiology-

In the last few decades there has been what appears to be a significant increase in the emergence of pathogenic infectious diseases such as Sudden Acute Respiratory Syndrome (SARS; emerging in SE Asia in 2002), Ebola Virus (sub-Saharan Africa, 1976), Human Immunodeficiency Virus (HIV; sub-Saharan Africa, 1970's), Marburg Virus (Sub-Saharan Africa, 1970's), and tick-borne diseases such as Lyme disease (NE USA, 1990's)(Daszak *et al.*, 2000). Among these recent discoveries are the hantaviruses, the causative agents of *Hantavirus* Pulmonary Syndrome (HPS; Western Hemisphere, 1993) and Hemorrhagic Fever with Renal Syndrome (HFRS; Eastern Hemisphere, 1950's). The appearance of these diseases are believed to be associated with a range of underlying causal factors including interactions with zoonotic pathogens, that would otherwise normally be contained within a host–parasite relationship, between wildlife and humans (Daszak *et al.*, 2000). The term "emerging infectious disease" (EID) has been coined to describe the plethora of pathogens implicated in these recent discoveries, and is specifically used to define diseases that have recently increased in occurrence or geographic range, moved into new host populations, or only recently been discovered (Daszak *et al.*, 2000).

In 1993 in the southwestern United States, an outbreak occurred of a previously unknown disease, now identified as *Hantavirus* Pulmonary Syndrome (HPS). The subsequent investigation led to the identification of the etiological agent—a novel hantavirus— *Sin Nombre* virus (SNV; Childs *et al.*, 1994; Nichol *et al.*, 1993). In the

years since this discovery, the number of *Hantavirus* geno– and serotypes identified in the Americas has grown to at least 23 (Johnson *et al.*, 1997; Morzunov *et al.*, 1998; Pini *et al.*, 2003; Rhodes *et al.*, 2000; Sanchez *et al.*, 2001; Schmaljohn *et al.*, 1995; Yates *et al.*, 2002), with this number on the increase as previously unknown hantaviruses are identified. In addition to *Sin Nombre* Virus some of the other most common hantaviruses known to cause HPS include; *New York* virus (NY), *Bayou* virus (BAY), *Black Creek Canal* virus (BCC), and *Andes* virus, with *Sin Nombre* virus being responsible for most of the 465 (Centers for Disease Control [CDC], 2007) known cases in the United States (Monroe *et al.*, 1999; Peters *et al.*, 1998; Schmaljohn *et al.*, 1997). Recent surveys for *Hantavirus* antibodies have revealed *Hantavirus*–infected rodents throughout most of North America (Holmes *et al.*, 2004; Monroe *et al.*, 1999; Rhodes *et al.*, 2000; Sanchez *et al.*, 2001; Schmaljohn *et al.*, 1995; Yates *et al.*, 2002). Hantaviruses have been proposed to be transmitted through aggressive encounters—primarily between individuals of the same sex (usually males)—or by infectious aerosols generated from contaminated urine, feces, blood, or saliva (Schmaljohn *et al.*, 1997; Olsson *et al.*, 2002).

Evolution-

It has been hypothesized by many that for every type of *Hantavirus* there is a specific rodent host species whose members can potentially acquire a chronic, asymptomatic, lifelong infection from the virus (Kaufman *et al.*, 1994; Morzunov *et al.*, 1998; Netski *et al.*, 1999). It has been shown through phylogenetic analyses that the topologies of the evolutionary relationships among hantaviruses were closely

correlated with those of their known or suspected primary mammal reservoirs (Borucki *et al.*, 2000; Monroe *et al.*, 1999; Plyusnin and Morzunov 2000; Sironen *et al.*, 2001; Yates *et al.*, 2002).

In the Americas, the deer mouse has been co–evolving with hantaviruses for approximately 12–20 million years, since the first cricetids crossed the Bering Land Bridge, radiating and differentiating into the Rodent subfamilies Neotominae and Sigmodontinae found in the New World today (Yates *et al.*, 2002). While much is known about deer mouse phylogeny, it remains less than fully understood, and as a result of the documented host-parasite specificity among deer mice and their hantaviruses (Yates *et al.*, 2002), the associated viral phylogeny may be unresolved as well. New species of Peromyscus are increasingly being revealed from among these former host conspecifics (Chirhart *et al.*, 2001; Zheng *et al.*, 2003), revealing the potential likelihood of many uncharacterized hantaviruses waiting to be described as well.

For many years it was believed that hantaviruses were maintained exclusively within Order Rodentia. Only very recently has that perception been challenged as genetically distinct hantaviruses have increasingly come to be found residing among members of the Order Soricomorpha (shrews) - family Soricidae (Xiao *et al.*, 1994; Arai *et al.*, 2007, 2008). In the former Soviet Union in the 1980's, antibodies to *Hantavirus* were found in members of families *Soricidae* and *Talpidae* (Gavrilovskaya *et al.*, 1983; Tkachenko *et al.*, 1983; Gligic *et al.*, 1989). At that time molecular techniques were not yet available to delineate genetic identity of potentially hosted viruses to confirm whether these were truly distinct viral evolutionary lineages or

merely cases of ecological spillover from a sympatric rodent host. As of yet, no human disease has been associated with shrew–borne hantaviruses (Arai *et al.* 2007).

Worldwide, most hantaviruses have been found in members of the rodent families Cricetidae (Subfamilies Neotominae and Arvicolinae) and Muridae (Subfamily Murinae), with genetically distinct viral lineages found associated with specific members of these taxa (Fig. 1). Hantaviruses are believed to have arisen at least 136 million years ago before the split of the Mammalian Orders Soricomorpha and Rodentia, evidenced by the presence of distinct hantaviral lineages found in both Orders (Carey *et al.*, 1971; Plyusnin *et al.*, 1996; Hughes and Friedman, 2000). Among the earliest described are those found in East Asia, including Hantaan virus from the Hantaan River valley, recognized during the Korean War, as well as Seoul virus, also found in Korea (Lee *et al.*, 1978)(fig. 3). These East Asian viral species have been found to be reservoired within members of the family Muridae, Subfamily Murinae, as *Apodemus agrarius* (Hantaan), and *Rattus norvegicus* (Seoul; Lee *et al.*, 1982). Another murine *Hantavirus* is the recently described Sangassou virus, shown to reside within the African wood mouse *Hylomyscus simus*, found in Sangassou, Guinea (Klempa *et al.*, 2006). Reducing the clarity of this strict regional relationship, but upholding the host Subfamily paradigm, is the presence of Dobrava virus found in Northern Europe and hosted by the murine *Apodemus flavicollis*, a congener of the Hantaan virus host (Avsic-Zupanc *et al.*, 1992; 2000). Phylogenetic analyses have supported placement of Dobrava virus in the murine-hosted viral clade (Avsic-Zupanc *et al.*, 1992) (Fig. 1). European and North Asian serotypes such as Tula virus, Topografov virus, and Puumala virus, among others, have been found within

arvicoline hosts such as *Microtus* and *Clethrionomys* species (Plyusnin *et al.*, 1994; Vapalahti *et al.*, 1999).

The more recently described members in *Hantavirus* are those found in the new world. In North and South America most of these infections are in species of the Subfamily Neotominae. Only a few Murid-hosted hantaviruses, consisting of Seoul virus in *Rattus norvegicus,* Subfamily Murinae, have been seen in the western hemisphere, primarily in urban environs (Monroe *et al.*, 1999). Cricetid rodents found hosting hantaviruses are many (table 1). In North America most common among these are hosts in the genus *Peromyscus* (Monroe *et al.*, 1999). The deer mouse, *Peromyscus maniculatus,* Subfamily Neotominae, has been identified as the reservoir for Sin Nombre virus (Childs *et al.*, 1994). In-depth studies of Sin Nombre virus in North America have shown substantial genetic diversity and geographic structure of genetic variants within the viral quasispecies that may be the result of the genetic diversity in *P. maniculatus* (Monroe *et al.*, 1999; Morzunov *et al.*, 1996; Nichol *et al.*, 1999; Plyusnin *et al.*, 1996; Plyusnin *et al.*, 2000; Salazar-Bravo *et al.*, 2002). This rodent genetic diversity is paralleled by that of the virus (Dragoo *et al.*, 2006). *Peromyscus maniculatus* as currently recognized have a vast range across the entire North American continent, excluding the southeastern U.S. (fig. 4). In addition, at least as many as 70 morphological subspecies are described in *P. maniculatus* (including sympatric subspecies), underscoring the variability in the species (Hall, 1981; Michaux *et al.*, 2001).

As pointed out by Wilson and Ruff (1999), the basis of the *Peromyscus* taxonomic framework was built upon morphological analyses, long before the advent of

molecular techniques. Recently, several former conspecifics, such as *P. maniculatus keeni, P. maniculatus sitkensis*; and congeners including *P. oreas* and *P. sitkensis* (now combined as *P. keeni)* have been removed from *maniculatus* and formally recognized as distinct taxa using chromosomal and molecular techniques (fig. 4) (Allard and Greenbaum, 1988; Avise *et al.*, 1983; Calhoun and Greenbaum, 1991; Chirhart *et al.*, 2005; Chirhart *et al.*, 2001; Greenbaum and Baker, 1978; Gunn, 1988; Hogan *et al.*, 1997; Hogan *et al.*, 1993; Michaux *et al.*, 2001; Smith *et al.*, 2000; Zheng *et al.*, 2003). Current literature has shown a wide range (2.5 - 16%) of intrageneric genetic divergence, being the percent difference in pair-wise comparisons of sequences, within *Peromyscus* (Bradley and Baker, 2001). In point of fact, Bradley and Baker (2001) show *Peromyscus boylii* only 2.5% genetically divergent from *P. simulus* in a well accepted sister (non-conspecific) relationship. In addition, much of the current data in the literature strongly suggest that co–speciation between hantaviruses and their hosts characterize the long–term evolution of these genera (Morzunov *et al.*, 1998; Yates *et al.*, 2002; Dragoo *et al.*, 2006).

While, as stated above, much analyses of *P. maniculatus* subspecies distributions have been morphologically based, analyses of hantaviruses have in contrast been undertaken using molecular techniques (Hjelle *et al.*, 1995a; Hjelle *et al.*, 1995b; Hjelle *et al.*, 1994; Johnson *et al.*, 1997; Li *et al.*,1995; Nichol *et al.*, 1993; Nichol *et al.*, 1999; Plyusnin and Morzunov, 2000; Dragoo *et al.*, 2006).

Virology-

Members of the genus *Hantavirus* of the family *Bunyaviridae* (5 genera, 250 species), are spherical, 100 nanometer diameter particles enclosed within a phospholipid bilayer envelope (Elliot *et al.*, 1991; Nichol *et al.*, 2005). Expressed within and extending above this envelope are two glycoproteins (G1 and G2) that facilitate cell entry via a clathrin coated pit (Elliot *et al.*, 1991; Nichol *et al.*, 2005). Within the envelope is a protein nucleocapsid that houses a segmented single-stranded negative-sense RNA genome ~12,100 nucleotides (nt) in length. These segments are small (S), medium (M), and large (L) (Plyusnin *et al.*, 1996). The S segment, approximately 2,000nt in length, encodes the genes for the nucleocapsid proteins that encase the RNA genome in daughter viral particles. The medium, or M segment (3,700nt), encodes the envelope glycoprotein precursor that is then co-translationally cleaved to yield the G1 and G2 glycoproteins (Elliot, 1990; Vapalahti *et al.*, 1992; Bohlman *et al.*, 2002). The L segment (6,500nt) encodes the RNA-specific polymerase that is used to replicate viral progeny genomes (Elliott *et al.*, 1991; Chizhikov *et al.*, 1995).

Purview of this study-

The genomes, or subsets thereof, of many different hantaviruses have been sequenced to varying extents (Schmaljohn *et al.*, 1990; Elliot *et al.*, 1991; Monroe *et al.*, 1999; Morzunov *et al.*, 1996; Nichol *et al.*, 1999; Plyusnin *et al.*, 1996, 2000; Salazar-Bravo *et al.*, 2002; Yates *et al.*, 2002). The majority of studies have chosen to examine the M segment (at the very least) as it is responsible for the glycoproteins used for cell

recognition, and thereby potentially the most variable since it is likely under the greatest amount of evolutionary pressure from the corresponding host. The L segment, coding for the RNA polymerase, is believed to be the most conserved of the *Hantavirus* genes (Schmaljohn, 1990; Elliott *et al.*, 1991; Chizhikov *et al.*, 1995). Many studies, especially those of hantaviruses with the greatest geographical proximity (and therefore *a priori* hypothesized to be the most genetically similar) to those found in the Pacific Northwest have used a fragment of the G1 and G2 encoding region of viral M segments, amplified by reverse transcriptase polymerase chain reaction (RT-PCR) (Avsic-Zupanc *et al.*, 2000; Hjelle *et al.*, 1995a; Hjelle *et al.*, 1995b; Hjelle *et al.*, 1994; Johnson *et al.*, 1997; Li *et al.*, 1995; Nichol *et al.*, 1993; Nichol, 1999; Plyusnin and Morzunov, 2000). Accordingly, to ensure that the viral analyses contained herein might be comparable across even the most potentially closely related species, similar M segment amplicons were pursued in this research. The PCR products were then sequenced and compared for genetic divergence as a direct indicator of viral speciation and for phylogenetic comparisons.

Mitochondrial DNA (mtDNA) is often the genetic material of choice for small mammal phylogenetic analyses (Avise *et al.*, 1983; Bradley *et al.*, 2001). Again, in order to enable meaningful comparison of Pacific Northwest specimens of mice, genus *Peromyscus*, to the bulk of data previously published, mtDNA was chosen for the analyses presented herein (Avise *et al.*, 1983; Allard *et al.*, 1988; Hogan *et al.*, 1993, 1997; Bradley *et al.*, 2001; Chirhart *et al.*, 2001; Michaux *et al.*, 2001; Zheng *et al.*, 2003).

To date, characterized hantaviruses geographically most proximal to the Pacific Northwest have been found in *Peromyscus*; indeed, all viruses associated with rodents in the genus *Peromyscus* form a well–supported monophyletic clade (Botten *et al.*, 2000; Monroe *et al.*, 1999; Plyusnin and Morzunov, 2000; Weidmann *et al.*, 2005; Yates *et al.*, 2002). This viral monophyly likely reflects adaptation of the virus to the rodent host and not just speciation due to geographic isolation of the virus variants (Botten *et al.*, 2000; Monroe *et al.*, 1999; Plyusnin and Morzunov, 2000; Weidmann *et al.*, 2005; Yates *et al.*, 2002). For instance, *P. maniculatus* and *P. leucopus* are sympatric in many regions and share microhabitat, but virus mixing between species is not seen (Monroe *et al.*, 1999). While extremely rare, cases of host switching (to hosts with no current *hantavirus* population), as well as spillover into neighboring species, do occur (Klingstrom *et al.*, 2002; Nemirov *et al.*, 2002; Vapalahti *et al.*, 1999; Weidmann *et al.*, 2005). Host switching is defined the result of formerly host-specific viruses having experienced genetic changes that allow the virus to be subsequently maintained in a different species population (Klingstrom *et al.*, 2002; Weidmann *et al.*, 2005). Spillover is the result of high population densities of the host species as well as another sympatric species leading, through increased encounters, to only a temporary presence (un-maintained) of the virus within that sympatric population, without any genetic change being seen in the virus (Nemirov *et al.*, 2002; Vapalahti *et al.*, 1999). A unique rodent host species would therefore be likely to have a novel *Hantavirus* as well. North American hantaviruses discovered among different rodent reservoir species have been found to range from one another in genetic percent divergence from as little as 5% to as much as 30% (Vincent *et al.*, 2000).

With so little known about *Hantavirus* distributions, it is important to understand the health risks faced by humans due to that lack of knowledge. Human mortality rates for HPS range from approximately 40% to 60% depending upon the strain of the virus encountered and the health and age of the patient (Peters, 1998; Schmaljohn and Hjelle, 1997). The current mortality rate among patients hospitalized and diagnosed with HPS in the U.S. is 38% but increases to 50% in Oregon. Three new cases occurred in Oregon during the span of this study with one of these three resulting in a fatality, underscoring the need for a clearer understanding of hantaviral species distributions.

No systematic studies of evolutionary relationships of deer mice have been undertaken in the Portland area or even Oregon in its entirety. Distribution maps show the Cascade Mountains forming a boundary between two subspecies of deer mice (fig. 4), with *Peromyscus maniculatus rubidus* on the West side, and *Peromyscus maniculatus gambelii* on the East (Michaux *et al.*, 2001; Wilson and Ruff, 1999; Hall, 1981), but with the upper habitation zone limits of both subspecies surpassing the passes within the Cascade Mountains, it is therefore likely that they constitute an incomplete barrier to migration, and it is suspected that some overlapping of populations may have occurred (Hall, 1981; Verts and Carraway, 1998; Wilson and Ruff, 1999). No molecular phylogenetic studies of Portland, OR region *Peromyscus* have previously been undertaken although, as previously mentioned, current phylogenies are based solely upon morphology, leading to the specific and sub-specific definitions described.

The objective of this research was to elucidate, using molecular analyses, whether the *Peromyscus* species found in the Portland area had been misidentified as well as to provide an initial characterization of the evolutionary relationships of the as yet uncharacterized regional *Hantavirus*. Hypothesized as:

$H_{0\text{-}1}$: Deer mice in the Portland, Oregon region are correctly classified as *Peromyscus maniculatus rubidus*.

Or, stated as a working hypothesis…

H_1: Based on molecular evidence, previously characterized *Peromyscus maniculatus rubidus* in the Portland, Oregon region, while a congener of *P. maniculatus*, is not conspecific.

$H_{0\text{-}2}$: The *Hantavirus* reservoired by deer mice in the Portland, Oregon region are in fact Sin Nombre virus.

Again, in working format…

H_2: The *Hantavirus* carried by the taxon currently recognized as *Peromyscus maniculatus rubidus*, constitutes a previously unrecognized species or strain of *Hantavirus*.

Hall (1981) suggested that the partially sympatric subspecies *P. m. rubidus* and *P. m. gambelii* may in fact not be interbreeding, although there have been no studies to confirm or deny this hypothesis (Hall, 1981). If this truly is the case, then according to the biological species concept (Mayr, 1982) some of these populations may have differentiated into recognizable distinct species.

In light of the foregoing research described above showing the gaps in our understanding of the biogeography of *Peromyscus*, as well as their hantaviruses, and in conjunction with the additional resolution to be provided by molecular analyses over morphological analyses alone (Hoelzel and Green, 1992), the reasoning for this research is evident. This study has attempted to yield a sharper image of the speciation patterns in the *Peromyscus maniculatus* species group, as well as the hantaviruses putatively coevolving with them, with a focus on the region in and around Portland, Oregon, and the greater Pacific Northwest.

Chapter 2: *Peromyscus* in the Pacific Northwest

Abstract-

The neotomine rodent *Peromyscus maniculatus* (deer mouse) is distributed and found throughout most of North America (fig. 3). With more than 70 subspecies described on a morphological basis (Hall, 1981; Osgood, 1909), evolutionary relationships among *Peromyscus maniculatus* subspecies, as well as those among the entire genus *Peromyscus*, remain complex and unclear. The research contained herein attempted to clarify some of these relationships, specifically the association of deer mice from the Pacific Northwest with their closest relatives, as well as their status within the larger generic taxonomic framework. To this end, phylogenetic analyses were performed on the mitochondrial DNA sequences of the ND3, ND4, ND4L, and Arginine tRNA from 84 individuals of *Peromyscus* representing the three putatively distinct subspecies from the Pacific Northwest. Specimens from beyond the Pacific Northwest region included subspecies from throughout the entire distribution of deer mice, including topotypical *Peromyscus maniculatus maniculatus* from Newfoundland. These sequences were compared to other congeners, including: *Peromyscus keeni, P. sejugis,* and *P. leucopus*, using Maximum Likelihood analysis with bootstrap support, genetic distance, and Bayesian analyses.

These molecular approaches to the problematic phylogenetic relationships among deer mice subspecies agreed in finding a taxonomic division in the molecular phylogeny of deer mice, separating *P. maniculatus* into two distinct clades. This division is equal in percent divergence to the divergence of *P. maniculatus* from *P. keeni* and *P. sejugis*. The division in the distribution of *P. maniculatus* occurs along

the Mississippi River and continues from its source in central Minnesota (after a 97 km break in the barrier) north along the Red River to Lake Winnipeg, then along the Nelson River to Hudson Bay essentially dividing *P. maniculatus* into an eastern and western clade along this barrier. The western clade may represent a separate—formerly cryptic—species, and is proposed in this investigation to be recognized as *Peromyscus sonoriensis.*

Introduction-

Description-

Peromyscus maniculatus, Order Rodentia, Family Cricetidae, Subfamily Neotominae, commonly known as the deer mouse, is a small, ubiquitous rodent with a range extending from the northeastern coast of North America across the continent to the west coast, north through most of Canada, and south into northern Mexico, but excluding most of the southeastern U.S. (fig. 3).

Peromyscus maniculatus varies in color from grayish to reddish-brown to black dorsally with a white venter, legs, and feet. The variation primarily depends on the habitat in which the population is found: color will generally tend toward the predominant local substrate. The tail is distinctly bi-colored, with dark above and white below (Huestis, 1931). Ears are large and semi–erect, and eyes are black and beady.

Adult *Peromyscus maniculatus* range from 10-30 grams with newborns at roughly 1.5-2 grams, and juveniles in the intervening range. Typically, adult deer mice will measure 106-222 mm in total length with tails from 46 to 123 mm, hind feet 14-25

mm, and ears 12-21mm (Hall, 1981). These wide ranges are seen as a result of the vast geographic range of the species (Hall, 1981). Local subspecies and populations exist within much smaller size ranges (Hall, 1981). A great deal of the variation seen throughout the deer mouse's range may also be seen on a smaller geographic scale in Oregon as a result of the highly disparate climates and habitats found on opposing sides of the Cascade mountains (Verts and Carraway, 1998; Woodley, 2007).

Habitat and Distribution-

Due to the vast range described above, *P. maniculatus* may be found in habitats as varied as agricultural fields, grassland, brushland, sub-alpine zones, northern boreal forest, desert, southern montane woodland, and dry subtropical climes. The species is most commonly found in prairies, bushy areas, and woodlands (King, 1968). In addition to these natural habitats, *P. maniculatus* is often seen in and around domestic dwellings.

The species has been divided into two subgroups: the grassland or prairie form in the Midwest and west, and the woodland form in the east and northeast (LTER, 1998). The woodland form of the east has a longer tail, ears, and hind foot than the more western prairie form. These differences have spawned controversy over whether or not they constitute distinct species.

Within the species' range as many as 70 subspecies of deer mice have been described (Hall, 1981; Michaux *et al.*, 2001) with some of these being sympatric and not considered to be interbreeding (Hall, 1981). To be considered a single species, some level of gene flow must occur among individuals throughout the range (Mayr,

1982). However, being a small organism with some relatively locally concentrated populations, it is clear that an individual *P. maniculatus* is incapable of migrating across the whole range. There also exist physical barriers within the range, such as the Rocky Mountains, Cascade Range, and Mississippi River, all of which serve to impede gene flow, thus isolating subspecies into allopatric populations. If these subspecies have not already diverged into separate species, they are therefore likely on that path.

Scope-

In consideration of the incomplete clarity of the phylogenetic relationships among members of the genus *Peromyscus*, this work was intended to use molecular data to test the monophyly of *Peromyscus maniculatus*, in particular, the subspecies from the Pacific Northwest currently assigned to *P. maniculatus*. While natural selection works upon phenotypes and not genotypes, the contents of genomes dictate those phenotypes. It is likely that molecular data will provide a more representative picture of evolutionary history than morphology because a portion phenotypic variation seen in/between species is the result of differential gene expression, not divergent genetic content.

Research Design and Methods-

Field Protocols-

Deer mice, *Peromyscus*, were collected from five sites in and around the Portland, Oregon metropolitan area from October 2002 through September 2004. Collection

sites were chosen based on their relative size to contain the trapping web. To ensure that samples were taken from locations where humans would be most likely to encounter infected mice, public parks were selected for specimen collection (fig. 5) (Kuenzi *et al.*, 2001). Sites chosen were: Forest Park, Multnomah Co., Tryon Creek State Park, Multnomah Co., Powell Butte Nature Park, Multnomah Co., Oxbow Regional Park, Multnomah Co., and Tualatin River National Wildlife Refuge (TRNWR), Washington Co.

The Forest Park site (5046892.5 N, 484267.53 E, UTM Zone 10, WGS-84), at a relatively flat 184 meters elevation near the top of the West Hills, on the northwest side of downtown Portland, consisted of a fairly dense second-growth mix of Douglas-fir (*Pseudotsuga menziesii*), western hemlock (*Tsuga heterophylla*), western red cedar (*Thuja plicata*), Oregon big-leaf maple (*Acer macrophyllum*), and red alder (*Alnus rubra*). Sword fern (*Polystichum munitum*), vine maple (*Acer cirinatum*), Oregon grape (*Berberis aquifolium*), and English ivy (*Hedera* helix) dominated the understory. Several trails crossed the study site, and were used daily by hikers, bikers, and dogs. While currently in a relatively natural state, it is known that this site has been logged in the past and replanted, in an attempt to restore a natural habitat. Other than the few hiking trails running through the area, it appears to have been left to develop along a natural course for many decades. The Tryon Creek State Park site (5031184.0 N, 474109.6 E, UTM Zone 10, WGS-84), at 105 m, on the south side of Portland contained essentially the same species composition as Forest Park, but with much greater proportion of ivy, a very undulating terrain, and two small creeks. The Tryon Creek research site was in an area of the park that did not have established trails

to or within it. Powell Butte Nature Park, is an extinct volcanic cinder cone on the east side of Portland, and the most anthropogenically altered of the sites with a relatively open canopy made up of big leaf maples and alders, with stinging nettles (*Urtica dioica*) and Himalayan blackberry (*Rubus discolor*) in the understory. This site, on the south shoulder of the summit at 135 meters (5036804.5 N, 461386.22 E, UTM Zone 10, WGS-84), had been logged thoroughly in the past and was flanked on the north by a large, maintained grass clearing. The Tualatin River National Wildlife Refuge (TRNWR), on the banks of the Tualatin River, was dominated by English Hawthorn (*Crataegus laevigata*) and Himalayan blackberry; it was mostly level, with dense vegetation, and wetlands encroaching into the site (34 m) (5026923.0 N, 486732.9 E, UTM Zone 10, WGS-84) during the rainy winter months. A newly established National Wildlife Refuge, the TRNWR had not yet opened to the public and had been temporarily left undisturbed to allow some reestablishment of the natural wildlife and ecology. Oxbow Regional Park on the Sandy River (site at 37 meters) (5037392.5 N, 445064.88 E, UTM Zone 10, WGS-84) is the only one of our sites containing a remnant patch of old growth forest. Douglas fir, western hemlock, and western red cedar almost completely shade the area. The ground is completely covered by sword fern, mosses, and large amounts of woody debris.

In addition to these five regular local collection centers, specimens were obtained from elsewhere in the range of *Peromyscus maniculatus* in order to provide comparative data (fig. 5). *Peromyscus maniculatus* tissues collected from the species type locality in northwestern Newfoundland were kindly donated by A. Lackey, State University of New York at Oswego. These tissues were included in the study to allow

direct comparison of local *P. maniculatus* genotypes to those representative of the voucher *P. m. maniculatus*. *Peromyscus* specimens also were collected from habitats adjacent to both the east and west of the Mississippi River in northeastern Missouri (west site) and western Illinois (east site); these specimens were collected and tissues generously donated by S. Burt, Truman State University, Kirksville, Missouri. It was hypothesized that these allopatric Missouri and Illinois populations, kept separate by the barrier of the Mississippi River, would provide a distinct and visible break in the genetic continuum (gradient) believed to reflect the *Peromyscus maniculatus* subspecies distribution across the continent (LTER, 1998; Dragoo *et al.*, 2006). This genetic continuum or gradient across the full range of *P. maniculatus* is seen as relative genetic similarity among subspecific populations, with that similarity inversely proportional to the geographic distance between subspecies.

Three types of live–capture traps were used to capture specimens: Sherman traps (H. B. Sherman Traps, Tallahassee, Florida), pitfall, and custom built mesh traps (O'Farrell et al., 1994). The Sherman traps were treadle-type collapsible aluminum boxes, models LFA and LFATDG, 8 cm x 8 cm x 23 cm. The mesh live traps were designed to be approximately the same size as the Sherman live-traps with square wire cloth creating the box. The closure mechanism consisted of a treadle trigger, and gravity drop door, both of galvanized metal (O'Farrell *et al.*, 1994). Pitfall traps consisted of a five-gallon bucket buried to the rim with a lid for a rain cover suspended above, leaving a 7-8 cm gap for specimen access. A trapping web design was selected over the more traditional trapping grid because absolute densities could be estimated from the capture data and because the estimation procedures required few

assumptions about capture probabilities and animal movement patterns (Parmenter *et al.*, 1998; Parmenter *et al.*, 2003; Wilson and Anderson, 1985).

The trapping webs used for this study consisted of 12 spokes radiating at 30–degrees from one-another from a center point (fig. 6). Each spoke measures 100 meters from the center to end and contains 12 trapping locations along its length. The first four traps are at 5–meter intervals, while the subsequent traps are 10 meters apart. Each trap station had a mesh and Sherman live–trap; trap stations 7 and 12 on each line also had a medium (48cm x 15cm x 15cm) or large (81cm x 25cm x 30cm) Tomahawk live–trap. In addition, trap stations 4, 7, and 12, of each line also had a pit fall trap as previously described. Lastly, 4 Sherman traps were located at the center–point of the web. This design results in 145 trap stations consisting of 144 mesh live-traps, 148 Sherman live-traps, 24 Tomahawk live-traps, and 36 pit fall traps (Parmenter *et al.*, 1998; Parmenter *et al.*, 2003) for a total of 353 traps. Mesh and Sherman traps were baited with a mixture of oats and peanut butter, while Tomahawk traps were baited with canned cat food. Pit falls remained unbaited. Poly-fiber nesting material was added to Sherman and mesh traps when warranted by weather. Traps were set out for four consecutive nights at each site with collection occurring at dawn the following day (Ritchie and Sullivan, 1989). After collection on the last morning, all Sherman and mesh traps were removed. To avoid extraneous captures, pitfalls were closed with a lid while not in use. Each park was trapped ten times over the course of this study, approximately every eight weeks. Total trap-nights were 65,200.

Captured animals were transferred from traps into clear, sealable plastic bags, labeled with the trap number, and transported to the center of the web for processing.

Captures from Tomahawk traps were left in the trap and also transported to the center of the web center. Due to the possibility of contracting HPS, standard precautionary methods were implemented, including the use of full-face powered air purifying respirators (PAPR) with highly efficient particulate air (HEPA) filters, and latex gloves under leather gloves (Mills *et al.*, 1995).

Each animal was identified to species and evaluated for gender, reproductive status, mass, relative age, and any other notable characteristics such as ectoparasites, wounds, or defects such as atypical coloration (appx. C). Heparinized glass micro-capillary tubes were used to draw blood from the retroorbital sinus and stored in cryovials, which were then placed in liquid nitrogen until testing (Kaufman *et al.*, 1994). After blood samples were taken, deer mice were euthanized in a chloroform chamber (Mills *et al., 1995*).

This research was conducted under the auspices of federal and state permits, and complied with the American Society of Mammalogists Guidelines (Gannon *et al.*, 2007) for the care and use of animals. Specimens were identified using museum tags including all relevant data mentioned above, sealed in plastic, then returned to the laboratory. Once in the laboratory, specimens were placed in a locked -70°C ultracold freezer for storage and further analyses.

Molecular Protocols-

Field collected blood samples were tested for the presence of antibodies cross-reactive to Sin Nombre virus (SNV) using Enzyme Linked Immunosorbent Assay (ELISA), by L. J. Dizney, Ph.D., of the Oregon State Health Laboratory, or Strip

Immunoblot Assay, by B. Hjelle, Ph.D., of the University of New Mexico, (SIA; Kaufman *et al.*, 1994; Mills *et al.*, 1995; Morzunov *et al.*, 1995; Rowe *et al.*, 1995).

Kidney samples were extracted from all *Peromyscus* specimens that were sero-positive for SNV antibodies as well as a random sample of those found negative (tables 2, 3; appx. D). Ultimately, including donated tissues from allopatric conspecifics (n=9) and congeners (n=4), tissues were collected for examination from 86 *Peromyscus* specimens.

Approximately 30-50 mg of tissue from each individual were used in DNA extraction. Whole cellular DNA was extracted and isolated from these tissue samples using the Qiagen DNeasy Tissue Kit (Valencia, CA) and protocols contained therein. To ensure comparison with sequence analyses in the literature, mitochondrial genes of the nicotinimide adenine dinucleotide (NADH) dehydrogenase subunit group were chosen as the targets for analysis. Specifically these consist of the ND3, ND4, ND4L, subunit mitochondrial genes and the Arginine tRNA mitochondrial gene that is located between the ND4L and the ND3 genes in the circular mitochondrial genome (Fig. 7). Amplification of gene targets was performed in two parallel but separate reactions for each DNA sample to obtain this entire gene set. Polymerase Chain Reactions (PCR) were set up utilizing Amersham Biosciences (UK) "puReTaq ready-To-Go PCR Beads" (each bead contains ~200μM final concentration dATP, dCTP, dGTP, and dTTP, 10mM Tris-HCl, 50mM KCl, 1.5mM $MgCl_2$), 0.4 μl (each) of 10.0 μM primers, and 1.0 μl of template DNA in a 25.0 μl final reaction volume. The first of the two fragments was amplified using the specific primers

5' – CGAACTAGTACAGCTGACTTCC – 3' (PI') for the (+) strand and 5' – CCGTAGGAGTTTGATAGTTTTGCT – 3' (MANR) for the (-) strand (Arevalo *et al.*, 1994). This PCR produced a mitochondrial DNA fragment of 734 bp. The second PCR reaction was set up with primers 5' – AGCAAAACTATCAAACTCCTACGG – 3' (MANF) (+) and 5' – TGGAGCTTCTACGTGGGCTTT – 3' (NAP2) (-), generating a 729 bp mitochondrial DNA fragment (Arevalo *et al.*, 1994). Reaction mixtures were placed in an Eppendorf – Master Cycler 96 well Thermocycler for PCR amplification. Thermocycler protocol (STANDARD) was delineated as:

Denature:	95°C	5min
35 cycles:	95°C	45sec
	50°C	30sec
	72°C	90sec
Extension:	72°C	10min
Hold:	4°C	

To verify successful PCR, the products from the reactions were evaluated using electrophoresis. 5 µl of amplified DNA product were combined with 12 µl water and mixed. These 17 µl solutions were then placed in each of the wells of an "E-Gel" (Invitrogen) 2% agarose gel. Lane one of the 12-lane gel was left empty to receive 10 µl of 80bp-1Kbp DNA ladder (Fermentas (Glen Bernie, MD) MassRuler™ DNA Ladder, Low Range) as well as 7 µl water. The gel was run for 15 minutes. After the run was complete the E-Gel was removed and placed on an ultraviolet viewer to

observe the fluorescently tagged DNA bands. In the E-Gel, fluorescent DNA stain is enclosed in the cartridge with the gel, allowing its interaction and binding with the DNA. Bands were seen, as expected, at the range of approximately 700bp-750bp as compared to the ladder.

After confirmation of PCR products the remaining reaction solutions were then subjected to PCR cleanup to remove excess polymerases, primers, dNTP's, and buffers using the QIAGEN (Valencia, CA) PCR Cleanup Kit and protocols contained therein.

The amplified products from each of these reactions were then utilized as template for sequencing using the modified Sanger chain terminator method (Sanger *et al.*, 1975, 1977). The sequencing reactions were set up with the 0.6 ml tubes recessed in an ice-bath to limit reactivity of constituents until placed in the thermocycler. Each reaction vessel was prepared with 2.0 µl Big Dye Terminator solution (Applied Biosystems), 2.1 µl of 2.5 µM appropriate primer, 1.0 µl 5x reaction buffer, 4.8 µl water, and 2.1 µl purified PCR product for a final reaction volume of 12 µl. These sequencing reaction vessels were then placed in the Eppendorf thermocycler and exposed to the sequencing thermo protocol (SEQ) as:

	96°C	5min
25 Cycles	96°C	30sec
	50°C	15sec
	60°C	4sec
Hold	4°C	

Upon completion of sequencing cycles, reactant solutions were plated in a 96 well micro titer plate that was then sealed and frozen at -70°C. The derived sequences were then shipped over night on dry ice to the Center for Genome Research and Bioinformatics (CGRB) Core Laboratories at Oregon State University, Corvallis, OR. There, sequences were analyzed on an Applied Biosystems (ABI) 3730 Capillary Sequence Machine.

Sequence File Preparation-

After the ABI 3730 generated the representative chromatograms they were downloaded via the internet from the CGRB Core Laboratories web site. Next, the sequence file chromatograms were uploaded into the software program SeqEd (Applied Biosystems v. 1.0.3). Within this program, sequences from corresponding primer pairs are viewed and edited for quality. First, the negative strand sequence, amplified from the reverse (ManR and Nap2) primers, is "reverse complimented" where the entire sequence is turned around to orient the last nucleotide first and the first nucleotide last. Then the bases of this reversed sequence are converted to their complementary nucleotide. Next, unidentifiable bases, artifacts of the sequencing process that occur at both the beginning and the end of the sequence, were removed. Sequences were aligned with SeqEd. These labeled mismatched bases were then examined based upon their corresponding peak in the sequence chromatogram. In most cases, one of the two opposing sequence chromatogram peaks was considerably cleaner, or stronger allowing the base to be "called" as the one indicative of the higher quality peak. In this way sequences were edited and aligned to produce a consensus

sequence for the target gene group from each individual *Peromyscus* specimen. This task was undertaken twice for each *Peromyscus* specimen because the target sequence (mitochondrial NAD gene group) was originally amplified and sequenced in two separate fragment subsets.

The two consensus sequence fragments from each specimen were concatenated in Text-Edit (Apple-Inc.). The concatenated sequences were imported into MacClade (Maddison and Maddison, 2003) for multiple sequence alignment where sequences from all *Peromyscus* were aligned with one another as well as with other out-group species obtained from NCBI GenBank. The multiple sequence alignment was adjusted as to codon reading frame to minimize the occurrence of stop codons and thereby represent the natural reading frame. The NADH dehydrogenase genes coded within the sequence contained the Arginine transfer RNA gene (between ND3 and ND4L) as well which is not translated into protein. Therefore, to separate the non-coding tRNA from the rest of the sequence, that is read in a triplet codon-reading frame, single spaces were inserted flanking the tRNA gene. In doing so, the tRNA was considered separately during phylogenetic analysis.

Phylogenetic Analysis-

The multiple sequence alignment file was saved in MacClade in Nexus format to allow use in the software programs PAUP (Phylogenetic Analysis Using Parsimony v. 4.0b10) (Swofford, 2002), MrBayes (v3.1.2) (Huelsenbeck and Ronquist, 2001), and GARLI (Genetic Algorithm for Rapid Likelihood Inference v 0.951) (Zwickl, 2006). The first step of phylogenetic analysis entailed selection of an evolutionary model to

enforce parameters of nucleotide substitution. To this end, the program MODELTEST v. 3.7 (Posada and Crandall, 1998) was utilized. Contained within the MODELTEST software package was the file modelblockPAUPb10. This file was inserted into the nexus sequence file and executed within PAUP. The purpose of this was to guide PAUP in analyzing the sequence data to choose from among 56 evolutionary models by using three different model selection frameworks: hierarchical likelihood ratio tests (hLRTs), Akaike information criterion (AIC), and Bayesian information criterion (BIC) (Posada and Crandall, 1998). The program also implements the assessment of model uncertainty and tools for model averaging and calculation of parameter importance, using the AIC or the BIC. Upon completion PAUP created an output file named *model.scores* that contained the results of the 56 analyses. The *model.scores* file was then read by MODELTEST that selected the model of nucleotide substitution that was the best fit. These analyses chose GTR+I+Γ (General Time Reversible + proportion Invariant + Gamma, 10 parameter) as the best fitting model. The GTR+I+Γ model is the most complex of the 56 model choices contained within the MODELTEST program where a proportion of sites are invariant (I) and a gamma-distributed substitution rate variation is implemented across sites (Γ). This more complex model allows more free parameters for the analyses. A command block for the purpose of directing PAUP in application of the evolutionary model, known as a model block, was rendered by MODELTEST and contained within the output file. Other PAUP block commands were added to the Nexus file as well to command PAUP to conduct further analyses.

These other commands included instructions for the type of analysis to be executed, in this case, Maximum Likelihood, which is a method for the inference of phylogeny. It evaluates a given hypothesis about the evolutionary history of the organisms involved (*Peromyscus*) in terms of the probability that the proposed model (GTR+I+Γ) and the hypothesized history would give rise to the observed data set. The supposition is that a phylogenetic history with a higher probability of reaching the observed state (condition of genetic divergence represented by the nucleotide data) is preferred to a history with a lower probability, or simply put, the higher probability phylogenetic history is more *likely*. The Maximum Likelihood method searches for the tree with the highest probability of occurrence.

In addition to Maximum Likelihood, Distance analysis (in PAUP) was used to evaluate the relative amount of genetic divergence among the *Peromyscus* included in this study. Distance provides a simple comparative matrix of the nucleotide differences among organisms stated as percent divergence.

Bayesian analyses, by way of MrBayes Markov chain Monte Carlo (MCMC) (Hulsenbeck and Ronquist, 2001) were also performed. Bayesian analysis, as implemented by MrBayes, uses the likelihood function as well but instead of testing the probability of the data given the hypothesis, Bayesian evaluates the probability of the hypothesis given the data. In Maximum Likelihood, free parameters are optimized, maximizing the likelihood, but in a Bayesian MCMC approach, free parameters are probability distributions, which are then sampled (Hulsenbeck and Ronquist, 2001).

Bayesian analysis expresses its result as the *posterior probability* (PP) of the tree

topologies and model parameters. The posterior probability is proportional to the likelihood, and, also proportional to the *prior probability* (Hulsenbeck and Ronquist, 2001). The best estimate of the phylogeny can be selected as the tree with the highest posterior probability (i.e., the MAximum Posterior probability [MAP] tree) (Rannala and Yang, 1996).

In a similar method to Bayesian posterior probabilities, Maximum Likelihood uses Bootstrapping (BS) (Felsenstein, 1985) to evaluate the probability that tree nodes are correct. These bootstrap values are reported as a percentage, being the percent of replicates that generated the same node. In the analyses conducted and described herein1000 bootstrap replicates were generated using PAUP and 1000 BS replicates were performed using the program GARLI.

Studies have shown some incongruity between Bootstrap and Posterior Probability (Leache and Reeder, 2002; Whittingham *et al.*, 2002). Although, when BS is plotted as a function of PP several examinations have revealed a correlation between BS and PP (Douady *et al.*, 2003). Rannala and Yang (1996) found that within this correlation, posterior probabilities are consistently higher than corresponding bootstrap percentages. Wilcox *et al.* (2002) found that both PP and BS are overly conservative estimates. Therefore, considering the higher PP results of Rannala and Yang (1996) and the fact that both are overly conservative (Wilcox *et al.*, 2002), it stands to reason that the Bayesian Posterior Probabilities may be slightly more representative of the true condition than Likelihood Bootstrap. That not withstanding, in a few circumstances, PP was found to have overestimated the hypothesis probability, and as such, over-reliance of Bayesian PP alone may be misleading (Douady *et al.*, 2003).

As a result of these findings both Bayesian Posterior Probabilities and Maximum Likelihood Bootstrapping have been included in these analyses to ensure the greatest possible representation of the *Peromyscus* phylogeny.

Results-

For comparison to five Rodent out-groups, consisting of *Microtus pennsylvanicus*, *Oryzomys palustrus*, *Sigmodon hispidus*, *Rattus norvegicus*, and *Reithrodontomys megalotis*, *Peromyscus maniculatus* mitochondrial ND3, ND4, ND4L, and arginine tRNA genes were sequenced (fig. 8) (appxs. E, G). Specimens included in these analyses were from the Portland, OR region (n=46), the greater Pacific Northwest (n=18), East-central California (n=1, *Peromyscus maniculatus rufinus*), the Midwest (n=9, *Peromyscus maniculatus bairdii, and P. leucopus*), and Newfoundland (n=4, *Peromyscus maniculatus maniculatus*), for a total of 78 sequence specimens generated by this study. Sequences for *Peromyscus keeni*, *Peromyscus leucopus* (one of six), and *Peromyscus sejugis* (n=2) were obtained from GenBank as well as the out-group sequences (n=5), These specific out-group species were selected due to their condition as known reservoirs of *Hantavirus* species.

Distance Analysis-

Distance analyses (*p* distances) (figs. 8, 9; appx. A) for 1,450 nucleotides of the mitochondrial ND3, ND4, and ND4L genes, as well as the Arginine tRNA sequence, revealed an average pair-wise nucleotide genetic distance (defined as percent divergence) of $p = 0.0413$ (4.13%) between the Newfoundland voucher *Peromyscus*

maniculatus maniculatus and the local *Peromyscus maniculatus rubidus* found west of the Cascade Mountains in Oregon (figs. 3, and 4). A relative pair-wise genetic distance of 0.0416 (figs. 8, 9) was found between voucher *P. m. maniculatus* and the greater Pacific Northwest (PNW) *Peromyscus maniculatus* subspecies clade (figs. 10-13) on the whole. Intra-PNW clade average genetic distance was found to be 0.0063 revealing no discernable structure signal (appx. A). In these analyses the PNW clade includes *P. m. rubidus*; *P. m. austerus,* from Washington, north of the Columbia River and west of the Cascade Mountains; *P. m. gambeli,* found east of the Cascade Mountains in Oregon and Northern California; and *P. m. austerus,* located in the San Juan Islands (fig. 4). At the same time, topo-typical *P. m. maniculatus* was shown to possess a genetic divergence of 0.0600 from the Pacific northwestern *P. keeni* (at least partially sympatric with the PNW *P. m.* clade), 0.0542 from *P. maniculatus rufinus*, the reservoir species of Sin Nombre Virus from the four corners region of New Mexico, and 0.0468 pair-wise genetic distance from *P. m. bairdii* from west of the Mississippi River in northeastern Missouri (figs. 8 and 9). This *P. m. bairdii/ P. m. maniculatus* pair-wise genetic distance (0.0468), taken with consideration that the genetic distance between the Pacific Northwest Clade and *P. m. bairdii* from the west side of the Mississippi River is only 0.0171, raises the possibility that a genetic break exists at or near the Mississippi River, dividing the *P. maniculatus* species into a western clade and an eastern Clade. Further to this point, when the *P. maniculatus baridii* subspecies from west of the Mississippi River are included with the Pacific Northwest specimens and compared as a group to the Newfoundland voucher specimens a pair-wise genetic distance of 0.0457 is resolved, strengthening the

possibility of two separate major *Peromyscus* (*maniculatus*) clades (figs. 8 and 9). Interestingly, the calculated genetic distance between two widely accepted species, *P. keeni*, from Washington and British Columbia (Zheng *et al.*, 2003), and *Peromyscus sejugis*, from San Diego and Santa Cruz Islands in the Gulf of California (Burt, 1932), is 0.0429, less than the other *P. maniculatus* subspecies in the western clade from the supposed conspecific *P. m. maniculatus* (figs. 8 and 9). *P. sejugis* itself has a similar genetic distance (0.0511), and is also recognized as a separate congener of *P. maniculatus* (fig. 8). That a previously described isolated insular species is only marginally more divergent (0.0511/0.0457) from the topo-type than are those from the rest of the western half of the continent as a whole raises the potential that speciation may have indeed occurred between the Newfoundland *Peromyscus maniculatus maniculatus* and the western *P. maniculatus* subspecies.

The Mississippi River only divides the majority of the United States, and not Canada, as it flows from West of Lake Superior in Central Minnesota to the Gulf of Mexico, therefore, it is an incomplete barrier for division of the entire North American *Peromyscus maniculatus* species distribution. Canadian populations may be similarly separated by a water barrier extending from Hudson Bay in the north to Lake Winnipeg (Lake Agassiz) via the Nelson River, and from there to the Lake of the Woods at the Canadian-Minnesota border, through the Boundary waters to the Mississippi River. The only opening in this barrier exists between the Red River, arising in Northern Minnesota, flowing to the southern tip of Lake Winnipeg, and the headwaters of the Mississippi River, a not so inconsequential 97 kilometers (60 mi.). Much more extensive sampling is required from these regions to further elucidate the

possibility of the occurrence of a genetic break within the *Peromyscus maniculatus* species along this mostly complete barrier.

Maximum Likelihood Analysis-

Taxa including *Peromyscus* genus and related outgroups (n=88) from within the rodent families Cricetidae and Muridae were examined for their phylogenetic relationship using Maximum Likelihood in PAUP (Swofford, 2002). Likelihood analyses rendered a likelihood tree with a negative log-likelihood (–lnL) = 8702.95284 for the resolved tree topology. The likelihood tree was calculated using the tree bisection-reconnection (TBR) swapping algorithm. Nucleotide frequencies were A=0.35450, T=0.29800, C=0.27910, G=0.06840. Among-site rate variation includes an assumed proportion of invariable sites of 0.2851. A gamma distribution of rates across variable sites was implemented with a shape parameter of 0.7693 and four rate categories. These parameters are determined by the GTR+I+Γ model of evolution as chosen by Modeltest (Posada and Crandall, 1998).

Node support for the likelihood tree was generated using 1000 bootstrap replicates. The consensus bootstrap tree yielded strong support for resolved nodes (Fig. 11). Fig. 11 shows the Pacific Northwest *Peromyscus* Clade (PNW) nested within a greater clade containing all those representative *Peromyscus* taxa from west of the Mississippi River (western clade). The consensus tree demonstrates the western *Peromyscus* clustering in a very well supported, yet distinct, clade, sister to the Newfoundland topotype specimens. The western clade is also separate at the same level from the other nearest (geographically and genetically) related congeners including *P. sejugis*

from San Diego and Santa Cruz Islands (Gulf of California) as well as *P. keeni* from the Pacific Northwest north of the Columbia River.

Consistent with widely accepted positions (Greenbaum *et al.*, 1978; Avise *et al.*, 1983) is the location in these analyses of *Peromyscus leucopus*, as a more distantly related member of the *Peromyscus* genus. As expected, all *Peromyscus* members represented in these analyses are seen as a separate monophyletic clade from the nearest regarded member of the Neotominae Subfamily that is included in these data, *Reithrodontomys megalotis*.

The genetic distance tree (fig. 10) resolved using the Neighbor Joining (NJ) method produced a tree with the same topology as the Bootstrapped Maximum Likelihood consensus tree (fig. 11). Branch lengths are shown above each corresponding branch with the change scale, representing the number of nucleotide changes from the previous node to the subsequent, located at the bottom-left of the figure. The Neighbor Joining analysis calculated a minimum evolution score of 3.18101 (analogous to sum of branch lengths) for these data.

A manually combined tree (fig. 12) includes branch lengths, likelihood scores, and bootstrap support at nodes present in both representative trees to allow direct comparison of these data.

Bayesian Analysis-

Bayesian analyses of these data were performed for 500,000 generations using two runs of four separate Markov chain Monte Carlo Metropolis coupling computations. Samples were taken from the tree-scape every 100 generations yielding 5,001 sample

trees for each run, or 10,002 total sample trees. The final average standard deviation of split frequencies was 0.0077 after completion of the 500,000 generations. The Metropolis-coupled Markov Chain Monte Carlo (MCMCMC) analysis led to burn-in after 100,000 generations, therefore, the first 1,000 sample trees were excluded from the majority-rule consensus tree search, resulting in a consensus tree derived from a total of 8,002 sample trees or 800,000 generations.

The Bayesian majority-rule consensus tree (Fig. 13) resolved the exact same topology as all other phylogenetic analyses contained herein (Likelihood, and Neighbor-Joining Distance), showing all subspecies of *Peromyscus* from west of the Mississippi River (that were included in this study) as one whole clade – sister at the same level to the topo-type *P. m. maniculatus* from Newfoundland as well as *P. keeni* and *P. sejugis*.

Discussion-

Peromyscus maniculatus is a diverse species said to span most of the North American continent, excluding the southeastern United States and extreme northern Canada (Hall, 1981). Included within this distribution are as many as 70 morphological subspecies (Hall, 1981; Michaux *et al.*, 2001). The vast majority of these sub specific relationships have not yet been evaluated by molecular analyses.

Being terrestrial and diminutive in size, deer mice possess limited vicariant abilities. With a home range of only 200-400 m^2 and highly susceptible to ecological barriers, they would therefore have great difficulty maintaining gene flow over this entire distribution (Hall, 1981; Verts and Carraway, 1998; Wilson and Ruff, 1999;

Michaux *et al.*, 2001). Without this exchange of genetic material, it is inevitable that allopatric populations would begin to genetically drift apart, or diverge (Mayr, 1982; Kimura, 1983). Winding through the middle of the North American continent is the Mississippi River that, along with the Red River in north central Minnesota, that flows to Lake Winnipeg (Lake Agassiz) in Canada and is ultimately connected to Hudson Bay via the Nelson River, come within 97 kilometers (60 miles) of completely dividing the continent in two. This very nearly complete ecological barrier may provide the very blockade to genetic exchange of flanking allopatric sub specific populations that could drive such a genetic drift. The literature focusing on *Peromyscus maniculatus* phylogenetic relationships are found with references to two distinct morphotypes, each consisting of many subspecies from within the species as a whole, the putative forest-form, found east of the Mississippi River and these other bodies of water, and the grassland-form, seen from west of the Mississippi River to the Pacific Ocean (LTER, 1998, Dragoo *et al.*, 2006).

In support of these previous findings, this study has resolved a similar division in the deer mouse distribution, in the form of a genetic break occurring at the Mississippi River. It should be noted however, that the discussion of a genetic break at this very specific location is based upon only four sequences from one site. It is apparent that the genetic break exists, only the exact location of it is in question. Further investigation into the populations distributed along this barrier would be needed to strengthen or refute these arguments.

Genetic distance analyses of the mitochondrial coding genes ND3, ND4, ND4L and the non-coding arginine tRNA, show the deer mouse subspecies nearest the

western banks of the Mississippi River, *P. m. bairdii*, virtually as genetically divergent (p distance=0.0468, figs. 8, 9) from the topotype *P. m. maniculatus* as are the western most deer mouse subspecies included in these analyses ({*P. m. rubidus, P. m. gambelii, P. m. austerus, P. m. rufinus*} at p=0.0457, figs. 8, 9). Conversely, the genetic distance between *P. m. bairdii* and these western subspecies is at most 0.0171, confirming their closer alliance with those western subspecies (figs. 8, 9). Interestingly, the haplotype distributions of the congener *P. leucopus*, with populations found on both sides of the Mississippi River, does not show this same division at the river (Morzunov *et al.*, 1998). One possible explanation for this lack of genetic division could be the result of more recent range expansion by *P. leucopus* than the expansion that led to the division in *P. maniculatus*. Simply, not enough time has passed since that expansion to make the division significant enough to be detected. In fact, Morzunov *et al.* (1998) show haplotypes of *P. leucopus* with "hydrid" haplotypes in over lapping regions of haplotype distributions. To that point, Morzunov *et al.* (1998) show that hantaviruses found in *P. leucopus*, with their more rapid genetic divergence than their hosts, do in fact show this division, with separate viral lineages found on opposite sides of the Mississippi River, and do not overlap. The faster genetic divergence of the viruses carried by *P. leucopus* may be revealing, through their own lineal division, a forthcoming division in the distribution of *P. leucopus*.

Distance analysis, with its susceptibility to underestimation of evolution due to the possibility of multiple changes at a given single nucleotide locus, would alone not be enough to confirm a division in *P. maniculatus*, or more importantly, clarify that *P. m. bairdii* is indeed clustering with those subspecies further west and not with the

Newfoundland topotype. Although, if underestimation is occurring, then correcting for that underestimation would only increase the resolved divergence, strengthening the argument for two separate east and west clades. Further phylogenetic analyses contained herein using methods less susceptible to underestimation of divergence reveal additional confirmation of the relationship espoused in these genetic distance analyses.

While considered an inferior phylogenetic method to the others used in these analyses - due to the simplicity of using least total branch length - Mihaescu *et al.* (2007) have shown that Neighbor Joining trees based upon genetic distance have proven to be reliable, and therefore worth inclusion in analyses. Genetic distance analysis may also suffer from one of the criticisms of Parsimony in that it may not be reflective of multiple changes within one nucleotide locus. This may result in an underestimate of the amount of change that may have historically occurred (Swofford, 1998). Conversely, with implementation of a more complex model (than used in Parsimony) such as GTR+I+Γ (used in these analyses), which allows a proportion of sites to be invariable (I), applies gamma-distributed variable rates (Γ), and among-site rate variation is taken into account, thereby alleviating at least most, if not all of the underestimation (Foster, 2003).

As expected, the distance Neighbor-Joining tree (Fig. 10), derived from the genetic distance matrix, separates the western subspecies of *P. maniculatus*, including *P. m. bairdii*, from the topotypical *P. maniculatus* at the species level, the same as the division between these and other previously accepted western congeners including *P.*

keeni, and *P. sejugis*. This association is repeated in other analyses as well. Fig. 11 shows the Bootstrapped Maximum Likelihood tree with the exact same topology as the NJ distance tree, showing all the subspecies from west of the Mississippi River contained within a single clade separate from, and at the same level as, the topotypical deer mouse. In point of fact, the node separating the western clade, the topotype, and *P. keeni* and *P. sejugis* in Fig. 11 was elucidated in 91% of 1000 bootstrap replicates.

There have been some purported advantages and disadvantages (Felsenstein, 1981; Cunningham *et al.*, 1998; Lewis, (CH 5 Soltis book 1998); Leache and Reeder, 2002) of Maximum Likelihood methods. Specifically, Maximum Likelihood methods have recently been preferred over other common methods such as Maximum Parsimony. Likelihood analyses often have lower variance than Parsimony, meaning, it is frequently the estimation method least affected by sampling error (Felsenstein, 1981). Analyses using Likelihood tend to be robust to many violations of the assumptions in the evolutionary model, and even with very short sequences they tend to outperform alternative methods such as Parsimony (Foster, 2003). Also, Likelihood considers branch length. Conversely, Parsimony assumes that you would have the same expectation that a character would change along both long and short branches of the phylogenetic tree. Likelihood and distance methods, using models, instead consider that change is more probable along long branches than along short branches and provide accurate branch lengths even when a particular site has undergone more than one mutation (Foster, 2003).

There have also been a few disadvantages proposed for Maximum Likelihood as well. While not detrimental to the quality of results, but possibly restrictive on the

number, depth, or types of analyses performed is the problem that Maximum Likelihood is very computationally intensive and thus extremely slow. Compared to Bayesian analysis, Maximum Likelihood has been shown to use 80% more computing time (Leache and Reeder, 2002). In these analyses, this has been alleviated to some extent by use of the research computer cluster at Portland State University. Another critique of Maximum Likelihood is that the result is dependent on the model of evolution used and therefore very susceptible to incorrect evolutionary model selection and application (Merl *et al.*, 2005).

One million generations of Bayesian analysis also resolved a phylogenetic tree (Fig. 13) that possessed the same topology as the Likelihood and Distance trees. The Majority-Rule consensus tree derived from the 800,000 sample trees, once again, partitions all western subspecies within a single clade, separate from Newfoundland deer mice at the same (species) level as they are split from *P. keeni* and *P. sejugis*. The Majority-Rule consensus tree contained a Bayesian posterior probability for this bipartition of 100, indicating the strongest possible probability of this node being representative of the natural state.

The results seen here displaying a clear division between the eastern and western clades are congruent with the conclusions reached by a concurrent study (Dragoo *et al.*, 2006). Dragoo *et al.* (2006) suggest in their analyses that further data were needed from Oregon to further the understanding of these relationships. These analyses have provided those data. Like Dragoo *et al.* (2006), the data contained herein have shown that *P. keeni* of the Pacific Northwest allies very closely with the insular *P. sejugis* of San Diego and Santa Cruz Islands in the Gulf of California. Conversely, while

Dragoo *et al.* (2006) suggest that coastal Pacific Northwest forms would ally more closely with *P. sejugis* and *P. keeni* than with *P. maniculatus*, these analyses, containing specimens from the coastal, insular, and non-coastal Pacific Northwest have resolved them as essentially equally distinct from *P. maniculatus* and the *P. keeni/sejugis* clade.

Therefore, it is concluded that deer mice in the western half of North America, possibly bound on the east by the Mississippi River and the northern bodies of water, and seen as the separate western clade resolved in Figs. 10-13, represent a formerly cryptic but distinct species from *Peromyscus maniculatus* in the east within the *Peromyscus* genus. As suggested elsewhere (Dragoo *et al.*, 2006), this western clade may be representative of the previously morphologically described taxon *Peromyscus sonoriensis* (Le Conte, 1853).

Chapter 3: *Hantavirus* in the Pacific Northwest

Abstract-

An outbreak of an illness in 1993 that came to be known as *Hantavirus* Pulmonary Syndrome (HPS) was later found to be caused by a novel *Hantavirus*, since named Sin Nombre virus. In the years since, as many as 34 previously unidentified hantaviruses have been discovered and characterized, with the vast majority of these occurring in the Western hemisphere. Until this study, no hantaviruses had been identified in Oregon in spite of the occurrence of five recognized cases of HPS in the state. To fill this gap, *Peromyscus maniculatus* (deer mice) were collected at 5 sites in parks and green-spaces in and around the Portland, OR region. Ultimately, 86 of 2084 (4.1%) deer mice sampled were found to be sero-positive for antibodies to *Hantavirus* (tables 1, 2; appx. D).

Phylogenetic analyses were performed on 23 *Hantavirus* sequences obtained from sero-positive deer mice in the Portland, Oregon region, with additional sequences (n=21) from other hantaviruses from GenBank included. Comparison of 617 nucleotides of the G1/G2 glycoprotein precursor gene from the medium (M) segment genomic RNA, to other hantaviruses from around the world, found the Oregon viruses to be 11.2 % divergent from the most closely related described *Hantavirus*, Convict Creek virus, from east-central California, 14.3% divergent from Sin Nombre virus, 21.5% from New York virus, 23.6% from Blue River virus, and 41.4% from Hantaan virus. Maximum Likelihood and Bayesian analyses found the Oregon viruses to be monophyletic with the Convict Creek and Sin Nombre viruses.

These data strongly suggest that the *Hantavirus* found in Oregon minimally constitutes a new strain, and may in fact be a new species. It is proposed here that this new virus be referred to as the Kalapuya virus.

Introduction-

Epizootiology-

In the last few decades there has been what appears to be a significant increase in the emergence of pathogenic infectious diseases such as Sudden Acute Respiratory Syndrome (SARS) (identified SE Asia, 2002), Ebola Virus (sub-Saharan Africa, 1976), Human Immunodeficiency Virus (HIV) (sub-Saharan, 1970's), Marburg Virus (Sub-Saharan Africa, 1970's), and tick-borne diseases such as Lyme disease (NE USA, 1990's). Among these recent discoveries are the hantaviruses, the causative agents of Hantavirus Pulmonary Syndrome (HPS) (Western Hemisphere, 1993) and Hemorrhagic Fever with Renal Syndrome (HFRS) (Eastern Hemisphere, 1950's). The appearance of these diseases is believed to be associated with a range of underlying causal factors including interactions with zoonotic pathogens, that would otherwise normally be contained within a host–parasite relationship, between wildlife and humans (Daszak *et al.*, 2000). The term "emerging infectious disease" (EID) has been coined to describe any of the plethora of pathogens implicated in these recent discoveries, and is specifically used to define diseases that have recently increased in occurrence or geographic range, moved into new host populations, or only recently been discovered (Daszak *et al.*, 2000).

In 1993 in the southwestern United States, an outbreak occurred of a previously unknown disease, now called *Hantavirus* Pulmonary Syndrome (HPS). The subsequent investigation led to the identification of the causative agent—a novel *Hantavirus*— *Sin Nombre* virus (SNV) (Childs *et al.*, 1994; Nichol *et al.*, 1993). In the years since this discovery, the number of *Hantavirus* geno– and serotypes identified in the Western Hemisphere has grown to at least 23 (Johnson *et al.*, 1997; Morzunov *et al.*, 1998; Pini *et al.*, 2003; Rhodes *et al.*, 2000; Sanchez *et al.*, 2001; Schmaljohn *et al.*, 1995; Yates *et al.*, 2002), with this number on the increase as previously unknown hantaviruses are identified. In addition to *Sin Nombre* Virus some of the other most common hantaviruses known to cause HPS include; *New York* virus (NY), *Bayou* virus (BAY), *Black Creek Canal* virus (BCC), and *Andes* virus, with *Sin Nombre* virus being responsible for most of the 465 (Centers for Disease Control [CDC] 2007) known cases in the United States (Monroe *et al.*, 1999; Peters *et al.*, 1998; Schmaljohn *et al.*, 1997). Recent surveys for *Hantavirus* antibodies have revealed *Hantavirus*–infected rodents throughout most of North America (Holmes *et al.*, 2004; Monroe *et al.*, 1999; Rhodes *et al.*, 2000; Sanchez *et al.*, 2001; Schmaljohn *et al.*, 1995; Yates *et al.*, 2002). Hantaviruses are often transmitted among rodents through aggressive encounters—primarily between individuals of the same sex, usually males, and by infectious aerosols generated from contaminated urine, feces, blood, and saliva (Schmaljohn *et al.*, 1997; Olsson *et al.*, 2002).

Description-

Members of the genus *Hantavirus* of the family *Bunyaviridae* (5 genera, 250 species), are spherical, 100 nanometer diameter particles enclosed within a phospholipid bilayer envelope (Elliot *et al.*, 1991; Nichol *et al.*, 2005). Present within and extending above this envelope are two glycoproteins (G1 and G2) that mediate false recognition of the viral particle as benign by the host target cell. The glycoproteins then facilitate cell entry via a clathrin coated pit (Elliot *et al.*, 1991; Nichol *et al.*, 2005). Within this envelope is a protein nucleocapsid that houses a segmented single-stranded negative-sense RNA genome ~12,100 nucleotides (nt) in length (fig. 14). These segments are small (S), medium (M), and large (L) (Plyusnin *et al.*, 1996). The S segment, approximately 2,000nt in length, encodes the genes for the nucleocapsid proteins that encase the RNA genome in daughter viral particles. The medium, or M segment (3700nt), encodes the envelope glycoprotein precursor that is then co-translationally cleaved to yield the G1 and G2 glycoproteins (Elliot, 1990; Vapalahti *et al.*, 1992; Bohlman *et al.*, 2002). The L segment (6,500nt) encodes the RNA-specific polymerase that is used to replicate viral progeny genomes (fig. 14) (Elliott *et al.*, 1991; Chizhikov *et al.*, 1995).

Natural History-

It has been hypothesized by many that for every type of *Hantavirus* there is a specific rodent host species whose members can potentially acquire a chronic, asymptomatic, lifelong viral infection (Kaufman *et al.*, 1994; Morzunov *et al.*, 1998;

Netski *et al.*, 1999). It has been shown through phylogenetic analyses that the topologies of the evolutionary relationships among hantaviruses were closely correlated with those of their known or suspected primary mammal reservoirs (Borucki *et al.*, 2000; Monroe *et al.*, 1999; Plyusnin and Morzunov 2000; Sironen *et al.*, 2001; Yates *et al.*, 2002).

In the Americas, *Peromyscus maniculatus* has been co–evolving with hantaviruses for approximately 12–20 million years, since the first cricetids crossed the Bering Land Bridge, radiating and differentiating into the Rodent subfamilies Neotominae and Sigmodontinae found in the New World today (Yates *et al.*, 2002). While much is known about deer mouse phylogeny, it remains less than fully understood, and as a result of the documented host-parasite specificity among deer mice and their hantaviruses (Yates *et al.*, 2002), the associated viral phylogeny may be unresolved as well. New species of Peromyscus are increasingly being revealed from among these former host conspecifics (Chirhart *et al.*, 2001; Zheng *et al.*, 2003), revealing the potential likelihood of many uncharacterized hantaviruses waiting to be described as well.

For many years it was believed that hantaviruses were maintained exclusively within Order Rodentia. Only very recently has that perception been challenged as genetically distinct hantaviruses have increasingly come to be found residing among members of the Order Soricomorpha (shrews) - family Soricidae (Xiao *et al.*, 1994; Arai *et al.*, 2007, 2008). In the 1980's, in the former Soviet Union, antibodies to *Hantavirus* were found in members of families *Soricidae* and *Talpidae* (Gavrilovskaya *et al.*, 1983; Tkachenko *et al.*, 1983; Gligic *et al.*, 1989). B y that time molecular

techniques were not yet available to delineate genetic identity of potentially hosted viruses to confirm whether these were truly distinct viral evolutionary lineages or merely cases of ecological spillover from a sympatric rodent host. As of yet, no human disease has been associated with shrew–borne hantaviruses (Arai *et al.* 2007).

Worldwide, most hantaviruses have been found in members of the rodent families Cricetidae (Subfamilies Neotominae and Arvicolinae) and Muridae (Subfamily Murinae), with genetically distinct viral lineages found associated with specific members of these taxa (Monroe *et al.*, 1999) (fig. 1). Hantaviruses are believed to have arisen at least 136 million years ago before the split of the Mammalian Orders Soricomorpha and Rodentia, evidenced by the presence of distinct hantaviral lineages found in both Orders (Carey *et al.*, 1971; Plyusnin *et al.*, 1996; Hughes and Friedman, 2000). Among the earliest described are those found in East Asia, including Hantaan virus from the Hantaan River valley, recognized during the Korean War, as well as Seoul virus, also found in Korea (Lee *et al.*, 1978)(fig. 3). These East Asian viral species have been found to be reservoired within members of the family Muridae, Subfamily Murinae, as *Apodemus agrarius* (Hantaan), and *Rattus norvegicus* (Seoul; Lee *et al.*, 1982). Another murine *Hantavirus* is the recently described Sangassou virus, shown to reside within the African wood mouse *Hylomyscus simus*, found in Sangassou, Guinea (Klempa *et al.*, 2006). Reducing the clarity of this strict regional relationship, but upholding the host Subfamily paradigm, is the presence of Dobrava virus found in Northern Europe and hosted by the murine *Apodemus flavicollis*, a congener of the Hantaan virus host (Avsic-Zupanc *et al.*, 1992; 2000). Phylogenetic analyses have supported placement of Dobrava virus in the murine-hosted viral clade

(Avsic-Zupanc *et al.*, 1992) (Figure 1). European and North Asian serotypes such as Tula virus, Topografov virus, and Puumala virus, among others, have been found within arvicoline hosts such as *Microtus* and *Clethrionomys* species (Plyusnin *et al.*, 1994; Vapalahti *et al.*, 1999).

The more recently described members in *Hantavirus* are those found in the new world. In North and South America most of these infections are in species of the Subfamily Neotominae. Only a few Murid-hosted hantaviruses, consisting of Seoul virus in *Rattus norvegicus,* Subfamily Murinae, have been seen in the western hemisphere, primarily in urban environs (Monroe *et al.*, 1999). Cricetid rodents found hosting hantaviruses are many (table 1). In North America most common among these are hosts in the genus *Peromyscus* (Monroe *et al.*, 1999). The deer mouse, *Peromyscus maniculatus,* Subfamily Neotominae, has been identified as the reservoir for Sin Nombre virus (Childs *et al.*, 1994). In depth studies of Sin Nombre virus in North America have shown substantial genetic diversity and geographic structure of genetic variants within the viral quasispecies that may be the result of the genetic diversity in *P. maniculatus* (Monroe *et al.*, 1999; Morzunov *et al.*, 1996; Nichol *et al.*, 1999; Plyusnin *et al.*, 1996; Plyusnin *et al.*, 2000; Salazar-Bravo *et al.*, 2002). The rodent genetic diversity is paralleled by that of the virus (Dragoo *et al.*, 2006).

Scope-

As described above, due to the recognized coevolution between Hantaviruses and their hosts, Hantaviruses are suspected to reside in nearly every (if not every) ecoregion where their potential host species are found. Therefore, the phylogenetic

relationships among members of *Hantavirus* are incomplete, as many Hantaviruses are believed to remain undiscovered and thus undescribed. In light of this, the purpose of this work was to obtain in the field, *Hantavirus* potentially existing in the Portland, Oregon region, and to use molecular data to characterize and test the phylogenetic position of the *Hantavirus* strain found in the local deer mice.

Research Design and Methods-

Field Protocols-

(refer to page 16, Chap. 2)

Molecular Protocols-

Field collected blood samples were tested for the presence of antibodies cross-reactive to Sin Nombre virus (SNV) using Enzyme Linked Immunosorbent Assay (ELISA), performed by L. J. Dizney of the Oregon State Health Laboratory, or Strip Immunoblot Assay (SIA), by B. Hjelle of the University of New Mexico (Kaufman *et al.*, 1994; Mills *et al.*, 1995; Morzunov *et al.*, 1995; Rowe *et al.*, 1995; Vincent *et al.*, 2000).

Lung tissue was extracted from all 86 *Peromyscus* specimens found to be sero-positive for SNV antibodies (tables 2, 3; appx. D).

Approximately 30-50 milligrams of tissue from each individual were used for RNA extraction. Frozen tissues were physically disrupted in liquid nitrogen (lN_2) by grinding with mortar and pestle. Ground tissues were then homogenized using the

"QiaShredder" kit (QIAGEN). RNA was extracted and purified from these tissue samples using the QIAGEN "RNeasy Tissue Kit". Also Hantaviral RNA was recovered from the blood serum of a human HPS patient from the Portland region. The viral RNA was obtained using the QIAGEN "QIAAmp Viral RNA Mini Kit" and protocols contained therein.

Two fragments of the hantaviral M segment (617 nucleotides combined), one each of the G1 (361nt) and G2 (256nt) glycoprotein precursor gene region, were chosen as the targets for analysis (Fig. 14). Viral RNA sequences were amplified in a one step process through primer specific reverse transcription (RT) followed by polymerase chain reaction (PCR) using the QIAGEN OneStep RT-PCR kit. Each reverse transcription and first round PCR reaction was set up in a single 50 µl reaction volume containing 16.0 µl RNase free water, 10.0 µl 5x QIAGEN OneStep RT-PCR buffer, 2.0 µl dNTP mix, 10.0 µl 5x Q-Solution, 2.0 µl QIAGEN OneStep RT-PCR enzyme mix, 1.0 µl RNase inhibitor, 2.0 µl each of first round primers at 10.0 µM concentration, and 5.0 µl of RNA template. Two of each of these reactions were prepared for each specimen, one for the G1 region and one for the G2 region. First round RT-PCR primers are G1 5'-ACAATGGGITCIATGGTITGTGTA-3' (SM1687C) and 5'-TTIAATITIICATCCAATCCA-3' (SM2255R) and G2 5'TGTGAITATCAAGGIAAIAC-3' (SM2779C) and 5'-ACIGTIGCICCATAIACAT-3' (SM3128R) (Johnson *et al.*, 1997). The RT-PCR reactions were set up on ice to prevent or slow any enzymatic catalysis from occurring before samples are placed in the thermocycler.

The RT-PCR was performed by placing the samples in an Eppendorf-Mastercycler 96 well and running the RT-PCR program, defined as follows:

30 min @ 50°C	RT reaction	
15 min @ 95°C	RT inactivated and DNA polymerase activated	
1 min @ 94°C	Template denaturation	25 cycles
1 min @ 62°C	Primer annealing	
1 min @ 72°C	Extension	
10 min @ 72°C	Final extension	

After RT-PCR was complete, reaction products were cleaned using the PCR Purification kit from QIAGEN. To verify successful PCR, the amplified products were evaluated using gel electrophoresis (agarose). 5 µl of amplified DNA product were combined with 12 µl water and mixed. These 17 µl solutions were then placed in each of the wells of an "E-Gel" (Invitrogen) 2% agarose gel. Lane one of the 12-lane gel was left empty to accommodate 10 µl of 80bp-1Kbp DNA ladder (Fermentas MassRuler™ DNA Ladder, Low Range) as well as 7 µl water. The gel was then placed in the Invitrogen E-Base and set to run for 30 minutes. After the run was complete the E-Gel was removed and placed on an ultraviolet viewer to illuminate the fluorescently labeled DNA bands.

When bands were found to be of the correct size (596 nucleotides (nt) for G1 and 350nt for G2), remaining products were then amplified further using hemi-nested primers inside those from RT-PCR. Second round nested primers for G1 (361nt) were 5'-GAITGIGAIACAGCAAAAGA-3' (SM1723C) and 5'-TCIGCACTIGCIGCCCA-

3' (ASM2016R). Hemi-nested primers for the G2 coding region (256nt) were SM2779C (as above) and 5'-CCCCAIGCICCITCAAT-3' (SM3020R) (Johnson *et al.*, 1997).

Second round hemi-nested PCR was set up utilizing Amersham Biosciences "puReTaq ready-To-Go PCR Beads" (each bead contains ~200μM final concentration dATP, dCTP, dGTP, and dTTP, 10mM Tris-HCl, 50mM KCl, 1.5mM $MgCl_2$, 0.4 μl (each) of 10.0 μM primers, and 1.0 μl of template DNA in a 25.0 μl final reaction volume.

Thermocycler protocol (PCR2) was delineated as:

5min @ 95°C	Initial Denaturation	
45sec @ 95°C	Template Denaturation	35 cycles
30sec @ 62°C	Primer Annealing	
90sec @ 72°C	Extension	
10min @ 72°C	Final Extension	
Hold @ 4°C		

Again, to verify successful PCR, the products from the hemi-nested reactions were evaluated using electrophoresis as delineated above. Bands were resolved, as expected, at the range of approximately 361nt and 256nt as designated by the nucleotide ladder.

After confirmation of PCR products the remaining reaction solutions were then subjected to PCR cleanup again to remove excess polymerases, primers, dNTP's, and buffers using the QIAGEN PCR Cleanup Kit and protocols contained therein.

The amplified products from each of these reactions were then utilized as template for sequencing using the modified Sanger chain terminator method. Each primer requires its own sequencing reaction resulting in four sequencing reactions for each original hantaviral sample (G1 set and G2 set). The sequencing reactions were set up with 0.6 ml micro centrifuge tubes recessed in an ice-bath to limit reactivity of constituents until placed in the thermocycler. Each reaction vessel was prepared with 2.0 µl Big Dye Terminator solution (Applied Biosystems), 2.1 µl of 2.5 µM appropriate primer (SM1723C, ASM2016R, SM2779C, SM3020R), 1.0 µl 5x reaction buffer, 4.8 µl water, and 2.1 µl purified PCR product for a final reaction volume of 12 µl. These sequencing reaction vessels were then placed in the Eppendorf thermocycler and exposed to the sequencing thermo protocol (SEQ) as:

	96°C	5min
25 Cycles	96°C	30sec
	50°C	15sec
	60°C	4sec
Hold	4°C	

Upon completion of sequencing cycles, reactant solutions were plated in a 96 well micro titer plate that was then sealed and frozen at -70°C. The sequence reaction products were then shipped over night on dry ice to the Center for Genome Research and Bioinformatics (CGRB) Core Laboratories at Oregon State University, Corvallis, OR. There, sequences were analyzed on an Applied Biosystems (ABI) 3730 Capillary Sequence Machine.

Sequence File Preparation-

After the ABI 3730 generated the representative chromatograms they were downloaded via the internet from the CGRB Core Laboratories web site. Next, the sequence file chromatograms were uploaded into the software program SeqEd (Applied Biosystems v. 1.0.3). Within this program, sequences from corresponding primer pairs are viewed and edited for quality. First, the negative strand sequence is "reverse complimented" where the entire sequence is turned around to orient the last nucleotide first and the first nucleotide last. Then the bases of this reversed sequence are converted to their complementary nucleotide. Next, unidentifiable bases that occur at both the beginning and the end of the sequence were removed. After this is done "comparative alignment" was selected in the program menu that asks the software to analyze and align the two sequences based upon where they are identical. To identify bases mismatched between the two sequences, a shadow sequence was generated that indicates those mismatches with an asterisk. These labeled mismatched bases were then examined based upon their corresponding peak in the sequence chromatogram. In most cases, one of the two opposing sequence peaks was considerably cleaner, or stronger allowing the base to be "called" as the one indicative of the higher quality peak. In this way sequences were edited and aligned to produce a consensus sequence for the target gene group from each hantaviral genomic segment. This task was undertaken twice for each viral sample representing the G1 and G2 coding regions, which were amplified and sequenced separately.

The G1 and G2 consensus sequence fragments from each specimen were concatenated in a text-editing program. The concatenated sequences were imported into MacClade (Maddison and Maddison, 2003) for multiple sequence alignment where sequences from all *Hantavirus* samples were aligned with one another as well as with other out-group species obtained from NCBI GenBank. The multiple sequence alignment (showing coded amino acids) was adjusted as to codon reading frame to represent the natural transcriptional reading frame. To allow separate adjustment of the G1 and G2 reading frames single spaces were inserted between the fragments.

Phylogenetic Analysis-

(refer to pg. 21, Chap. 2)

Results-

Distance Analyses-

In these analyses *Hantavirus* sequences were obtained (n=22; appxs. F, H) from *Peromyscus* in the greater Portland, OR region. In addition, a twenty-third *Hantavirus* sequence was obtained from the blood of a current HPS patient. Based upon a 617 nucleotide fragment of the M segment RNA, glycoprotein precursor gene, Oregon hantaviruses were sequenced for comparison to other hantaviruses (sequences from GenBank, appx. F) from North America and the rest of the world. Genetic divergence (p distance) analysis was conducted using PAUP (Swofford, 1998). Figure 15 and appendix B contain pair-wise genetic distances for the Portland viruses relative to

most other North American (Cricetidae-borne) hantaviruses and others from throughout the world (Muridae-borne). Both uncorrected and corrected genetic distance data are shown. Corrected genetic distances were calculated by application of the general time reversible model of evolution allowing a proportion of sites to be invariant with a gamma distribution of that variance across sites (GTR+I+Γ). Most publications report uncorrected genetic distances, so these will be the focus here for more clarity of comparison.

The Portland area *hantavirus* referred to as Kalapuya virus (KV) here (after the original inhabitants of the Willamette Valley – the Kalapuya tribe), possesses an uncorrected genetic distance of 0.112 (fig. 15) from its nearest known (geographically and genetically) congener, Convict Creek virus (CC) found in the eastern Sierra Nevada Mountains in east-central California (Schmaljohn *et al.*, 1995). Intra-specific average nucleotide genetic distance for the Portland area hantaviruses was 0.017, indicating the lack of diversity expected within a local population (Monroe *et al.*, 1999). Included among these Kalapuya viruses is the sequence recovered from a Washington County, OR human patient serum. This sequence had a genetic distance of 0.014 from Kalapuya virus sequences found in mice from the patients home and 0.016 from the whole of KV. Viral sequences WC7 and WC13 were identical to one another and both most resembled the patient virus at p= 0.008, less than half the distance of the patient virus from the other sequences recovered from the patients home, making it likely that one of the these two mice may have originally possessed the virus(es) that infected the patient (appx. B).

The next nearest (p=0.143) described *Hantavirus* after CC is Sin Nombre virus (SNV) from the four corners region in the American Southwest (Childs *et al.*, 1994). *Peromyscus*-borne hantaviruses in the American west are collectively known as the Sin Nombre-like group (Morzunov *et al.*, 1997). Within this western North American region is El Moro Canyon virus (EMC) from southern California, but as seen in Figs. 16-18, El Moro Canyon virus is not within the Sin Nombre group and is in fact quite divergent with a p=0.278 from the Portland area virus and p=0.269 from Sin Nombre. Fig. 15 also reveals two other hantaviruses from west of the Mississippi River in Blue River virus (BR) hosted by *Peromyscus leucopus* (western haplotype), and Bayou virus (BV) reservoired by *Oryzomys palustrus*. Similar to El Moro Canyon virus, Bayou virus (p=0.273) is quite divergent from Portland and also is not from within the Sin Nombre group (figs. 16-18). Blue River virus (p=0.236) while also significantly divergent from Sin Nombre, is reservoired by a Peromyscine, and therefore is considered part of the Sin Nombre-like group (Morzunov *et al.*, 1997). Of note, Blue River virus has also been described from Indiana (Morzunov *et al.*, 1997) but BR sequences used in these analyses were derived from Oklahoman specimens.

Other more genetically distant hantaviruses seen in Fig. 15 are New York virus (NY) reservoired by the eastern haplotype of *P. leucopus*, and Black Creek Canal virus from south Florida found in *Sigmodon hispidus*. New York virus is shown to possess a genetic distance of 0.215 from Portland virus, similar to the other *P. leucopus* virus, Blue River at 0.236. The final *Hantavirus* seen in Fig. 15 is Prospect Hill virus found in the Northeastern United States and hosted by the arvicoline *Microtus pennsylvanicus*. Not known to cause human disease, Prospect Hill virus is

the most genetically divergent *Hantavirus* in North America with a p=0.331 from Kalapuya virus.

Maximum Likelihood Analysis-

The *Hantavirus* sequences examined with genetic distance methods were also subjected to Maximum Likelihood analysis. Using the GTR+I+Γ model of evolution as chosen by MODELTEST (Posada and Crandall, 1998), maximum likelihood analyses using PAUP (Swofford, 2002) resolved a tree with a score of –lnL=8011.8281 and an Akaike Information Criterion (AIC) of 16043.6562. The likelihood tree was calculated using the tree bisection-reconnection (TBR) swapping algorithm. Nucleotide frequencies were A=0.33470, T=0.30010, C=0.16080, G=0.20440. Among-site rate variation includes an assumed proportion of invariable sites of 0.1364. A gamma distribution of rates across variable sites was implemented with a shape parameter of 0.5469 and four rate categories. Node support for the likelihood tree was generated using 1000 bootstrap replicates.

Similar to the genetic distance tree in Fig. 16, the boot strapped Maximum Likelihood tree in Fig. 17 shows the Portland virus as sister to Convict Creek virus. This same clade is also nested in Sin Nombre virus. Each of these nodes is supported above 90 percent, with the separation of the Portland virus from Convict Creek in 990 of 1000 bootstrap replicates. Differing from the genetic distance tree, the likelihood tree places El Moro Canyon virus outside of the Sin Nombre-like *Hantavirus* clade, more in line with previous research (Hjelle *et al.*, 1994; Morzunov *et al.*, 1997; Vapalahti *et al.*, 1999; Vincent *et al.*, 2000). Supported at 97 percent the three

arvicoline viruses, Prospect Hill, Tula virus, and Puumala virus, were separated in a single clade revealing their genetic similarity with one another but in contrast with their geographic disparity. The node containing these divisions was supported in 1000 of 1000 replicates. Bayou and Black Creek Canal viruses formed their own clade. Although only tepidly supported, all South American hantaviruses were contained within a single clade as well. Fig. 17 shows all of the New World *Hantavirus* clades nested within and monophyletic from Seoul virus. The cricetid (neotomine, sigmodontine, and arvicoline) hantaviruses in Fig. 17 are found nested within the Asian, European, and African murine hantaviruses (Hantaan, Dobrava, and Sangassou viruses).

Bayesian Analysis-

Summarized consensus tree data may be viewed in Fig. 18 with posterior probabilities shown for each bifurcation. The Majority-Rule Bayesian consensus tree yielded a topology very similar to the genetic distance tree (Fig. 16) and similar to the maximum likelihood (Fig. 17) phylogeny. In Fig. 18 the Portland virus is found sister to Convict Creek virus, which in turn is sister to Sin Nombre virus. These western United States hantaviruses are seen sister to the eastern U.S. hantaviruses, New York, and Blue River. These Sin Nombre-like hantaviruses form a single monophyletic clade sister to the clade found to contain the South American hantaviruses and the two southeastern U.S. hantaviruses, Bayou and Black Creek canal. In the same fashion as the likelihood tree in Fig. 17, the Bayesian tree in Fig. 18 also reveals the *R. megalotis* reservoired El Moro Canyon virus outside of each of these clades that are nested

within EMC in the Bayesian tree but not the Neighbor-Joining distance tree (Fig. 16). In the Bayesian analysis the two major clades described above, along with El Moro Canyon virus, are nested in the three arvicoline hantaviruses, Prospect Hill, Puumala, and Tula. Again, as seen in the likelihood tree, the neotomine and arvicoline *Hantavirus* clades are nested in the murine hantaviruses from Europe, Asia, and Africa.

Discussion-

Phylogenetic analyses of Kalapuya virus (KV) were based upon 617 nucleotides of the medium (M) segment genomic RNA. This particular fragment of the genome was selected for these analyses because the envelope glycoproteins are used for host cell entry and quite possibly under the most selective pressure, making it a prime location for divergence in the genome. In addition, most literature on this subject use this region of the genome, making these data directly comparable to the rest of the literature. This fragment codes for two portions of the glycoprotein precursor gene, corresponding to segments of the G1 and G2 coding regions. Figures 17 and 18 have revealed the robustness of these analyses by showing the pair-wise genetic distances among commonly evaluated hantaviruses to be nearly identical to those resolved by Morzunov *et al.* (1998). For example, using M segment data, Morzunov *et al.* (1998) found Sin Nombre virus (SNV) to be at a genetic distance of 0.183 from another Sin Nombre group virus, New York virus, while these data herein show 0.189, also similar is Sin Nombre to Blue River at 0.195 / 0.201, and Sin Nombre to El Moro Canyon at 0.288 / 0.269. This congruity lends strength to the pair-wise genetic distances

resolved by these analyses between the previously un-described Kalapuya virus and Sin Nombre virus (p=0.143), as well as the genetic distances between KV and Convict Creek virus (CC) (p=0.112) and CC and SNV (p=0.130). Convict Creek virus has been characterized as at least a new strain of *Hantavirus* within the Sin Nombre group, if not a new species (Schmaljohn *et al.*, 1995; Li *et al.*, 1995). If Convict Creek virus has been classified as distinct from Sin Nombre, then, so too should Kalapuya virus, found at an even greater genetic distance from SNV than is CC.

Hjelle *et al.* (1995a), and Morzunov *et al.* (1998) have proposed that three lines of evidence be considered when evaluating hantaviruses for possible speciation. First is immunological by using plaque reduction neutralization assays (PRNA), where neutralizing species specific antibodies are bound to viral particles and infection susceptible cells are exposed to the resulting virus-antibody complex. Then speciation is defined by at least a four-fold, two-way difference between putative species, described as the known virus species having four times as much antibody binding (and therefore neutralization) as unknown comparative hantavirus species. The second uses ecological or physiological evidence as found in the viral host. For viral speciation to have occurred, it must be found in a distinct rodent host, known to reservoir no other *Hantavirus*. Morzunov *et al.* (1998) proposed the adoption of the definition of a different rodent host as "a reproductively and/or ecologically and/or geographically separated rodent species *or subspecies*, which carries a phylogenetically distinct *Hantavirus* and which is capable of being the sole carrier of this virus in a rodent community". Third, molecular evidence must reveal significant nucleotide differences from other described hantaviruses. Puthavathana *et al.* (1993) proposed, which has

since been adopted elsewhere, that *Hantavirus* speciation is said to have occurred at more than a 25% nucleotide difference in the glycoprotein precursor gene open reading frame. A nucleotide difference of 15 to 25% was considered a "grey area" where phylogenetic analyses are then required for proper evaluation of speciation (Puthavathana *et al.*, 1993).

In consideration of these criteria, the results of the analyses contained herein are discussed further. In terms of immunological evidence, even though Sin Nombre virus (SNV) has been adapted to cell culture, this examination is not currently possible as the Portland *Hantavirus* has yet to be adapted to cell culture, for which hantaviruses are notoriously difficult, thereby prohibiting the PRNA.

Criterion two, ecological or physiological evidence, is also difficult to evaluate. What is known, is the hosts of SNV and KV are geographically isolated from one another with the SNV host, *P. m. rufinus*, found in the four corners region, some 1,700 kilometers (1,100 miles) from western Oregon. In general terms, the vast difference in the disparate climes occupied by these conspecific hosts (temperate rain forest in western Oregon compared to scrub desert in the four corners region) leads to the logical conclusion that these two hosts, however defined, are also ecologically isolated from one another. Not known is the level of reproductive isolation that may exist between these two hosts, as those examinations have yet to be conducted. Not addressed by Hjelle *et al.* (1995a), but appropriately included in the discussion of different hosts, is the phylogenetic relationship between the two hosts based upon molecular evidence. As has been discussed previously, rodent phylogeny, and especially that among *Peromyscus*, is unresolved. Rodent phylogenies produced in

these analyses, seen in Figs. 11 through 14 reveal the distinct possibility that *Peromyscus maniculatus rubidus*, from which the Kalapuya viruses were obtained, may in fact be a distinct species (along with other nearby allopatric subspecies) from the topo-typical *Peromyscus maniculatus maniculatus*. Making this assessment more difficult is the lack of a comparable sequence (mtDNA ND3, ND4, and ND4L) from the Convict Creek host to have allowed its inclusion in the *Peromyscus* phylogeny. The pair-wise genetic distance between the SNV reservoir, *P. m. rufinus*, and *P. m. rubidus* is seen at 0.025 (figs. 8, 9). While this level of divergence is below the typical speciation threshold for rodents of roughly 4%, Fig. 8 does show that *P. m. rubidus* is, as stated above, quite likely a separate species from *P. m. maniculatus* with a pair-wise genetic distance of 4.1%. Moreover, the Bayesian tree seen in Fig. 13 shows the Pacific Northwest subspecies as a separate clade nested within *P. m. rufinus*.

The lack of complete data for more thorough analyses of the first two criteria has resulted in greater emphasis placed on the third criterion, molecular evidence. Molecular and phylogenetic evidence is the focus of these analyses and has revealed Kalapuya virus with a genetic distance from Sin Nombre virus of 0.143, less than the definitive threshold for speciation as proposed by Puthavathana *et al.* (1993) of 25%, is, however, near the lower limit of the "grey area" that was discussed by the same authors.

Maximum Likelihood and Bayesian phylogenetic analyses contained herein (Figs. 18-19) have strengthened the genetic distance analysis that found Kalapuya virus nested within and monophyletic to Convict Creek and Sin Nombre viruses. As all three are hosted by subspecies of *P. maniculatus*, and considering other North

American hantaviruses, reservoired by the congener *P. leucopus*, are also recognized as part of the Sin Nombre group, this monophyly was expected.

In light of the pair-wise genetic distance as found at the lower limit of the grey area criterion and its relative phylogenetic location strongly within the Sin Nombre group, it may be argued by some that the Kalapuya virus has not yet speciated. That said, the level of genetic divergence from Sin Nombre virus does strongly argue that KV is on a separate evolutionary trajectory and are at the very least nearing speciation, if that level of distinction has not yet been achieved. The findings of the *Peromyscus* phylogenetic, geographic, and ecological relationships discussed above lend themselves to this argument. Further analysis of the complete Kalapuya virus genome, even greater elucidation of the host relationships through further molecular comparison as well as immunological analyses may in fact lead to such a specific classification in the near future. It is therefore concluded that Kalapuya virus – in honor of the first human inhabitants of the Portland, OR region, may in fact be a previously un-described species of *Hantavirus*, and minimally constitutes a new strain.

Chapter 4: *Peromyscus* and *Hantavirus* Coevolution

Abstract-

It has been proposed that hantaviruses are found in a species-specific relationship with their hosts and have experienced a co-evolutionary history. Phylogenetic analyses performed here have been found in support of these studies and revealed the probability of the presence of a new deer mouse species, minimally in Oregon, if not including much of the western United States. As suggested by others, this western deer mouse in Oregon is referred to as *Peromyscus sonoriensis rubidus*. In light of the co-evolutionary relationship, as well as further phylogenetic analyses contained herein, the hantavirus reservoired by *P. s. rubidus* is in fact a new quasi-species of hantavirus, separate from Sin Nombre virus and Convict Creek virus, proposed as Kalapuya virus.

Methods:

Sets of hantavirus and host sequence specimens, as described in chapters 2 and 3, were reduced to a subset of specimens consisting of only those from North America, including from elsewhere only Hantaan virus and its host, *Rattus norvegicus* for out-group comparison. Bayesian analyses were performed on these two sets of data using the same Bayesian protocols as described in chapter 2 (pg. 36). The two resulting majority-rule trees were aligned for comparison after rotating the host tree to its mirror image.

Results:

In addition to the previously discussed observations for individual phylogenies of hantaviruses and hosts a comparative Bayesian double phylogenetic tree of these hantaviruses and hosts is seen in Fig. 19. Included on the left of this figure are most of the hantaviruses from North America, excluding only those found in a reservoir already represented here by another *Hantavirus*, and the other significant mile-post *Hantavirus*, Hantaan virus from Korea, as the out-group. The right side of the figure shows the known reservoirs for these hantaviruses. With consistently strong posterior probabilities (PP>96), the comparative phylogenies are also found to be near perfect mirror images of one another.

Only the location within the tree of El Moro Canyon virus relative to its known host, *Reithrodontomys megalotis*, is in dischord with parallel evolutionary histories. While *R. megalotis* is found more closely allied with other *Peromyscus*, El Moro Canyon virus is associated with hantaviruses (Bayou, Black Creek Canal) hosted by more distantly related Sigmodontines (*O. palustrus*, *S. hispidus*).

Discussion-

Peromyscus speciation-

Recently, Dragoo *et al.* (2006) recognized the hantavirus-host co-evolutionary framework in a more geographically comprehensive study in which the authors recognized six separate *Peromyscus* clades or lineages but, as noted by the authors, missing from their analyses are data from Oregon. Of those lineages found, one that was suggested existed in the Pacific Northwest coastal region. It was also proposed

that an expanding Rocky Mountain clade is overlapping with this coastal clade, said to include *P. keeni*, *P. sejugis*, and *P. maniculatus gambelii* (Dragoo *et al.*, 2006). Conflicting with this proposal is the fact that *Peromyscus* analysed in this study included *P. m. gambelii* from east of the Cascade Mountains in Oregon that were not seen to be significantly different from *P. m. rubidus,* on the west side of the Cascades. Also, these analyses found the Oregonian deer mice to be slightly more distant from the coastal *P. keeni/sejugis* clade (0.0556) than the *P. m. maniculatus* (0.0416) clade from central-northeastern North America, west of the St. Lawrence River, but very closely associated with the Rocky Mountain clade (0.0248). Contrary to Dragoo *et al.* (2006), Washington coastal *P. m. austerus*, which might have been assumed to reside with the coastal clade were not found associated with the coastal clade as hypothesized by those authors, but instead correlated very closely with the other conspecifics *P. m. rubidus*, and *P. m. gambelii* (Figs. 10-13) from Oregon, seen here linked to the Rocky Mountain clade (Figs. 8, 9). Therefore these data in conjunction with those found by Dragoo *et al.* (2006) suggest that there may in fact be several distinct deer mouse lineages in western North America, with those from Oregon, and possibly Washington as well, associating with the Rocky Mountain clade and not the Coastal clade. In addition, the analyses contained herein align with the findings of Hogan *et al.* (1997), and Dragoo *et al.* (2006) in suggesting that a deep genetic division occurs between the greater western North American and the eastern North American deer mouse clades, with this break (as proposed here) along the Mississippi River corridor. It has been proposed by Dragoo *et al.* (2006) that the Rocky Mountain clade may represent the previously described morpho-species *Peromyscus sonoriensis* (Le Conte, 1853).

Hantavirus speciation and Coevolution-

Phylogenetic trees seen in Figs. 17-19 as well as the pair-wise genetic distances in Fig. 15 reveal Kalapuya virus (KV) closely associated with Convict Creek Virus (CC) (p=0.112) and Sin Nombre Virus (SNV) (0.143), all of which are reservoired by putative hosts (*P. m. sonoriensis* and *P. m. rufinus* respectively) found to reside within the Rocky Mountain clade (proposed as *P. sonoriensis*).

The *Hantavirus*/host double phylogeny seen in Fig. 19 displays the suggested co-phylogeny implied by the co-evolution seen between hantaviruses and hosts. The intrigue of this figure is borne-out by the virtually identical topologies of these two trees, only the split between El Moro Canyon virus (EMC) and the nested clade containing Bayou virus (BAY) and Black Creek Canal virus (BCC) differs from the reservoir tree topology for these taxa in that the reservoir tree places the hosts for BAY and BCC (*Oryzomys palustrus* and *Sigmodon hispidus* respectively) as a clade sister to, instead of nested within the EMC host (*Reithrodontomys megalotis*) as is seen for the virus tree. All other hantaviruses examined in Fig. 19, including Kalapuya virus, are found in a perfect mirror-image association with their putative reservoirs, representing mirrored, or co-evolution.

Conclusions-

Peromyscus maniculatus rufinus in the southwestern United States has for the past 14 years been considered to be the reservoir of Sin Nombre *Hantavirus* (Childs *et al.*, 1994). *Peromyscus maniculatus sonoriensis* in eastern California has been recognized

as the host for Convict Creek virus for the last 13 years (Schmaljohn *et al.*, 1995). Armed with the knowledge that species of the genus *Hantavirus* are associated with specific host species, and that both virus and host evolve within this co-evolutionary framework (Monroe *et al.*, 1999; Dragoo *et al.*, 2006), and that the Portland (and likely all western) deer mouse range is composed of what may in actuality be a species distinct from *P. maniculatus sensu stricto*, it is reasonable to hypothesize that hantaviruses found in these reproductively isolated "*P. maniculatus*" populations also will have undergone a similar level of differentiation into a putatively novel viral species distinguishable from Sin Nombre virus at a molecular level. The data contained herein bear that out. It is therefore concluded that Kalapuya virus, found in Oregon deer mice, is a formerly undescribed species of *Hantavirus*, and the Oregon deer mouse, its reservoir, is in fact a separate species of the western deer mouse clade proposed as *Peromyscus sonoriensis*.

Also supported is the hypothesis that coevolution of North American hantaviruses with their hosts is seen in the presence of essentially identical phylogenetic topologies.

Epilogue: Research Significance

In 1993 an outbreak of a previously unrecognized disease occurred in the four corners region of the southwestern United States. Subsequently, phylogenetic analyses of the etiological agent for this disease was identified as a formerly undescribed member of the viral genus *Hantavirus* (Family Bunyaviridae) (Childs *et al.*, 1994). Sin Nombre virus was the moniker given to this new pathogen with the associated pathology described as *Hantavirus* pulmonary syndrome (HPS). With an initial mortality rate of more than 70%, HPS is characterized by bilateral pulmonary infiltrates, resulting in pulmonary deficiency and sometimes, failure. While no direct treatment yet exists, mortality has recently been reduced to 38% through early recognition and subsequent fluid management.

Clouding the understanding of patterns of HPS occurrence is the fact that among the characterized hantaviruses (>40) as many as 20 have not been known to cause disease. Even within the pathogenic group of hantaviruses there exist those with varying degrees of pathogenicity, where some may illicit only minor symptoms instead of the full illness.

The division between pathogenic versus non-pathogenic viral lineage is partially reflected in the reservoir phylogenies. Worldwide, hantaviruses have been recognized in specific mammalian hosts and in the New World, Plyusnin and Morzunov (2001) and others have found a great amount of association among hantaviruses and their hosts. In fact Yates *et al.* (2002) recognized that Sin Nombre virus, and therefore other Sin Nombre-group hantaviruses, were not introduced to the western hemisphere but instead, during the mid-Miocene, migrated and co-evolved in a very close

relationship with their hosts as their reservoirs crossed the Bering land-bridge from Asia to North America, entered the New World, and then radiated and differentiated into the Neotominae and Sigmodontinae currently found there. In the process, those resident hantaviruses differentiated as well into the hantaviral lineages currently seen in the western hemisphere. For many years studies suggested these hosts resided only within Order Rodentia. Recently, however, new viral lineages have been described from Soricid reservoirs (*Blarina spp.* and *Sorex spp.*) (Arai *et al.*, 2006, 2007) but to date, no Soricid-borne *hantavirus* has been associated with human disease. There exist, of course, Murid-borne hantaviruses as well that do not generate disease within humans, especially those found within the Arvicolinae such as one North American *hantavirus*, Prospect Hill virus, reservoired by the Arvicoline *Microtus pennsylvanicus*.

With the knowledge that hantaviruses are associated with specific mammalian hosts, and are not ubiquitously pathogenic, there arises, therefore, the need for a greater understanding of the distribution of hantavirus hosts (potential and recognized) as well as the putative virus strains themselves. The data contained herein contribute to that growing level of clarity of hantaviral-reservoir evolutionary, phylogenetic, and biogeographic associations. The theory espoused by Dragoo *et al.* (2006) that deer mouse phylogenies provide a framework, at least potentially, for the elucidation of the distribution of hantaviruses and their phylogenetic relationships to one another are supported by the findings reported here. In point of fact, Dragoo *et al.* (2006) state that missing from their data are specimens from Oregon of both deer mice and their potential hantaviruses. Again, at the conclusion of this study, those data are now

provided. As acknowledged previously above, these analyses have shown that there exists an extreme likelihood that the deer mice from Oregon, likely in conjunction with other subspecies in the western United States, are in fact a new species separate from *Peromyscus maniculatus sensu-stricto*. In addition, the hantaviruses reservoired by the Oregon deer mice represent a new strain, if not a new species, as well. Taken in consideration with the variability of pathogenicity seen in the various *Hantavirus* strains and species, the new taxonomic designation for Oregon deer mice fills a gap in the current knowledge of those distributions in the Pacific Northwest. This becomes critical when the virulence of the Oregon *Hantavirus* is taken into account. As of this publication, nine cases of HPS have been documented in Oregon with four of those nine (0.44) resulting in death. While rare, any disease that is known to result in a 44% mortality rate warrants efforts to understand as much about its epizootiological, phylogenetic, and biogeographic characteristics as possible. Hantaviruses are referred to as emerging infectious diseases (EID), and as humans expand their environment further into natural habitat and more regularly encounter potential wildlife carriers of disease it is critical that the scientific community endeavor to facilitate the understanding of these disease parameters to gain a greater awareness of all the different quasispecies of hantavirus in nature today and the ranges in which they occur. This knowledge will allow a concentration of management efforts of the associated reservoir species, especially those that carry the most dangerous strains of hantavirus, to raise local community awareness and insofar as possible limit the amount of human exposure to the pathogens potentially carried by the mice.

On a genetic scale, the viral sequences elucidated in these analyses were derived from the envelope glycoprotein-coding region of the viral tripartite genomic RNA. These co-translationally cleaved glycoproteins, G1 and G2, are expressed within and upon the phospholipid bilayer envelope that is procured from the infected cell, which surrounds and encloses the daughter virion. The envelope glycoproteins are believed to play a significant role in cellular recognition, binding of the virus particle to a clathrin coated pit, and subsequent cellular uptake of the virion.

Although attempts have been made, there currently exists no vaccine to inoculate against, or antiviral drug for the treatment of, HPS. Efforts to construct a vaccine to *Hantavirus* have involved utilization of G1 and G2 based upon previously mentioned fact that those glycoproteins play such a large role in the infection process. By focusing sequencing efforts on the envelope glycoprotein precursor coding gene, basal knowledge for the amino acid, and therefore the protein structure, may be extrapolated from those sequences for further application of the study of the interactions involved at the molecular level in the host cell mediated uptake of the virus particle at the clathrin coated pit.

Procurement of pathogens from their sources, in this case, hantaviruses from deer mice, followed by evaluation of their defining characteristics, epizootiology, and distributions are the first steps in working to avoid and/or offset their ultimate pathology. By identifying and characterizing the *Hantavirus* from Oregon, as well as its reservoir species, these analyses have contributed to the greater effort to reduce and understand *Hantavirus* Pulmonary Syndrome.

Figure 5: Specimen Collection Sites. Image A: map of Portland, OR, U.S.A. showing field collection sites of *Peromyscus maniculatus* in the metropolitan area. Concentric blue and light blue rings marks the locations of two recent HPS cases. Image B: locations of specimens from outside Portland, OR. Sequences not from Oregon, Missouri, Illinois, and Labrador were obtained from GenBank.

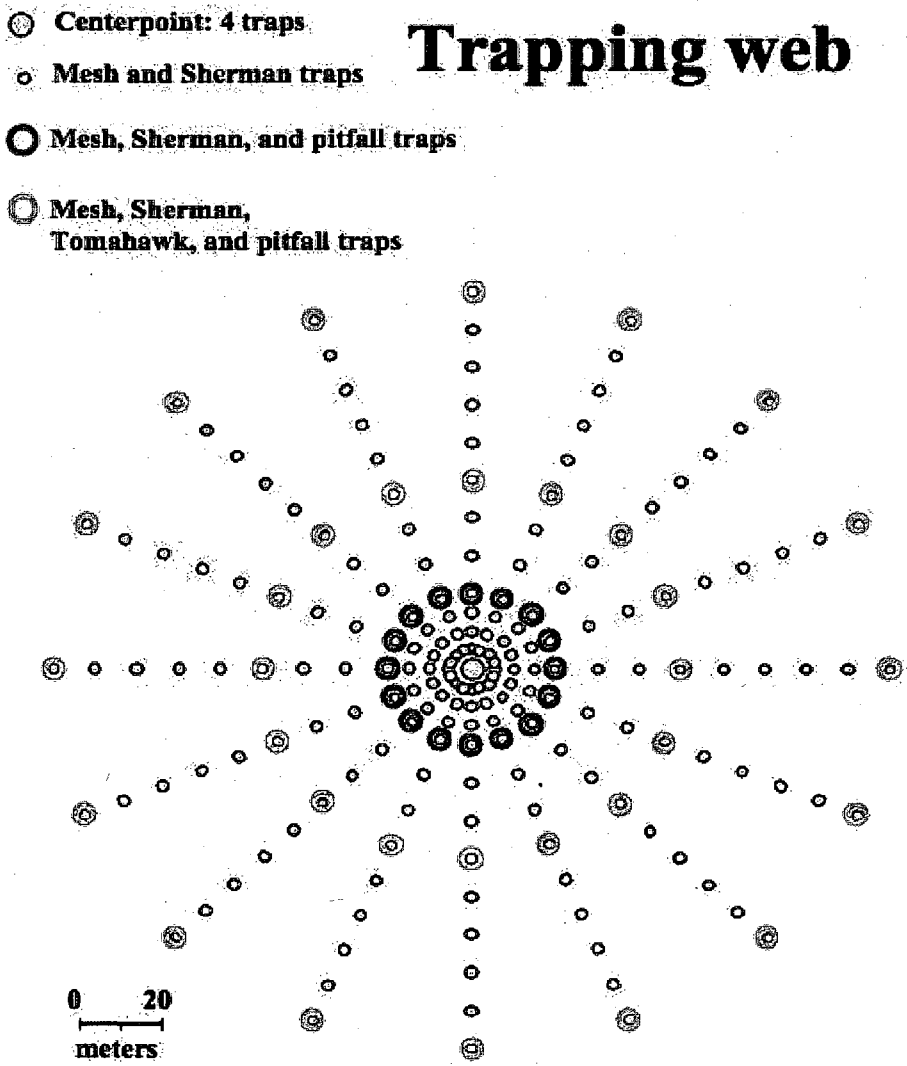

Figure 6: Small Mammal Trapping Web (used for this study). Consists of 12 trap lines radiating and numbered from center at 30° apart, each containing 12 trap stations. Each line is 100m in length from center point with trap stations 1-4 at five-meter intervals on each line. Subsequent stations 5-12 are at 10m. Light blue dots are stations with Sherman and Mesh live traps. Those with dark blue rings include pitfall traps along with the Sherman and mesh live traps. Brown rings add a Tomahawk trap to the other three trap types.

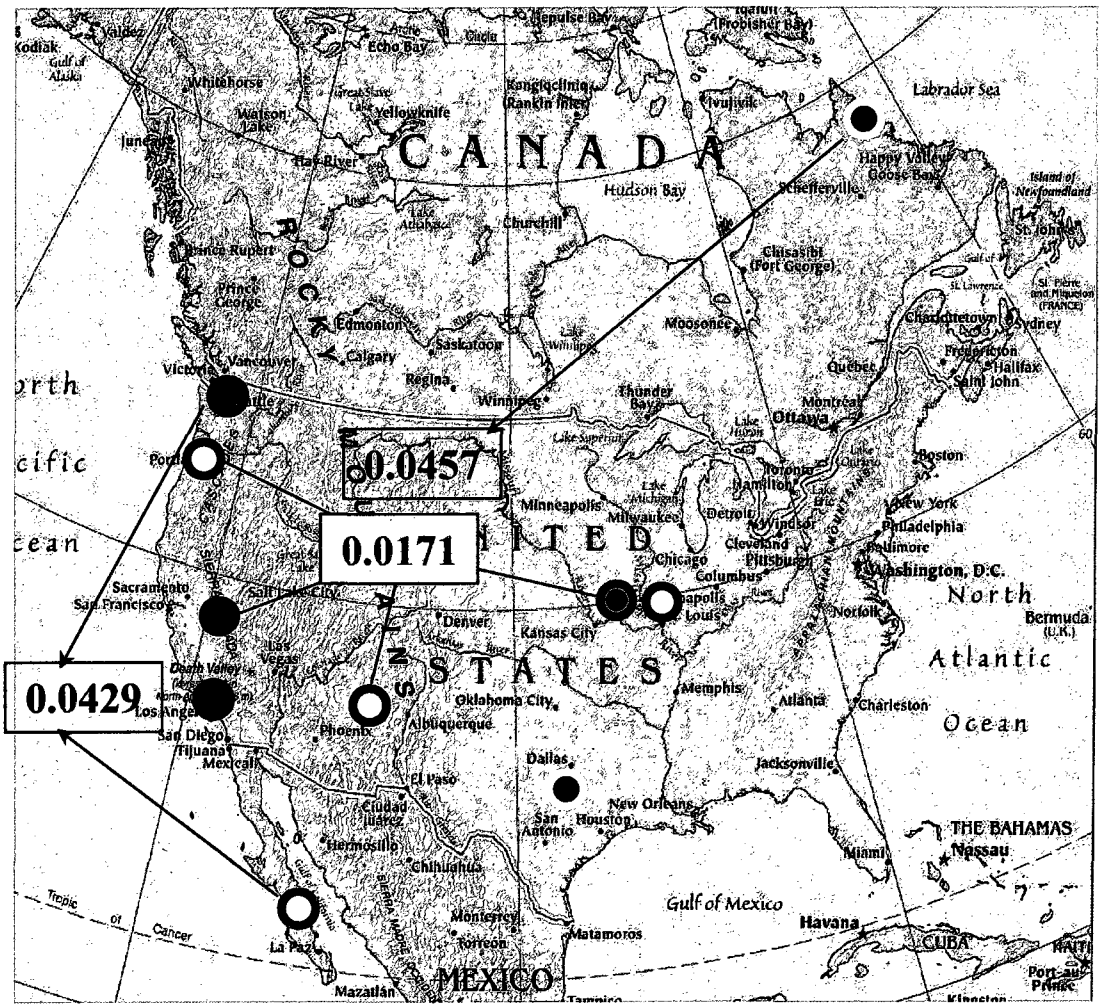
	PNW	*R. megalotis*	●	0.5613
	P.m.m.	*R. megalotis*		0.5906
	P. m. bairdii	*R. megalotis*		0.5783

Figure 8: *Peromyscus* Pair-wise Distances. Pair-wise comparison of average percent genetic difference in mitochondrial ND3, ND4, and ND4L genes (1,463bp) between *Peromyscus* (including *R. megalotis*) species and subspecies (n=84). Non-Neotomine sequences not shown – see Appendix A for full pair-wise distance matrix. PNW clade=*P. m. rubidus, P. m. gambelii, P. m. austerus*. Color coded dots correspond to specimen collection locations on map.



● = *Peromyscus maniculatus rubidus/gambeli/austerus*

● = *Peromyscus maniculatus rufinus*

● = *Peromyscus maniculatus sonoriensis*

● = *Peromyscus maniculatus bairdii*

● = *Peromyscus maniculatus maniculatus*

● = *Peromyscus keeni*

● = *Peromyscus sejugis*

● ● = *Peromyscus leucopus*

● = *Reithrodontomys megalotis*

Figure 9: *Peromyscus* Pair-wise Nucleotide Distance Physical Map. Genetic distance of mitochondrial ND3, ND4, ND4L, and arginine tRNA genes of rodents relevant to the phylogenetic position of *Peromyscus* in the Portland, OR region. *P. leucopus* is represented by two separate haplotypes. Data in red indicates average intra-specific distance among western North American clade.

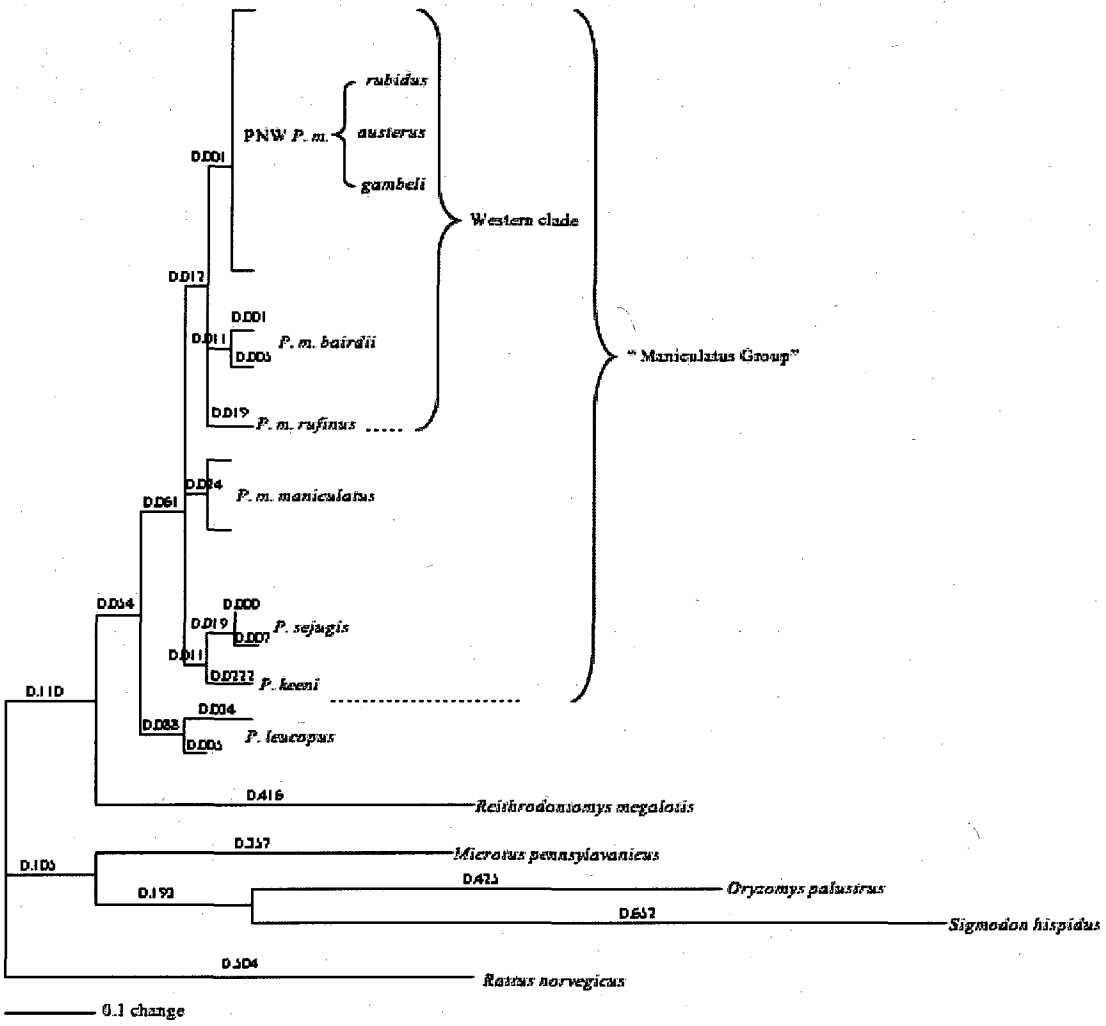


Figure 10: *Peromyscus* Distance Tree. Neighbor-Joining tree of *Peromyscus* and outgroups (n=88) resolved from distance analysis of mitochondrial ND3, ND4, ND4L, and arginine tRNA genes (1,463bp). Numbers represent branch length as changes genetic distance from preceding node. PNW = Pacific Northwest. "Western clade" is west of the Mississippi River. "Maniculatus Group" includes PNW and Western clades.

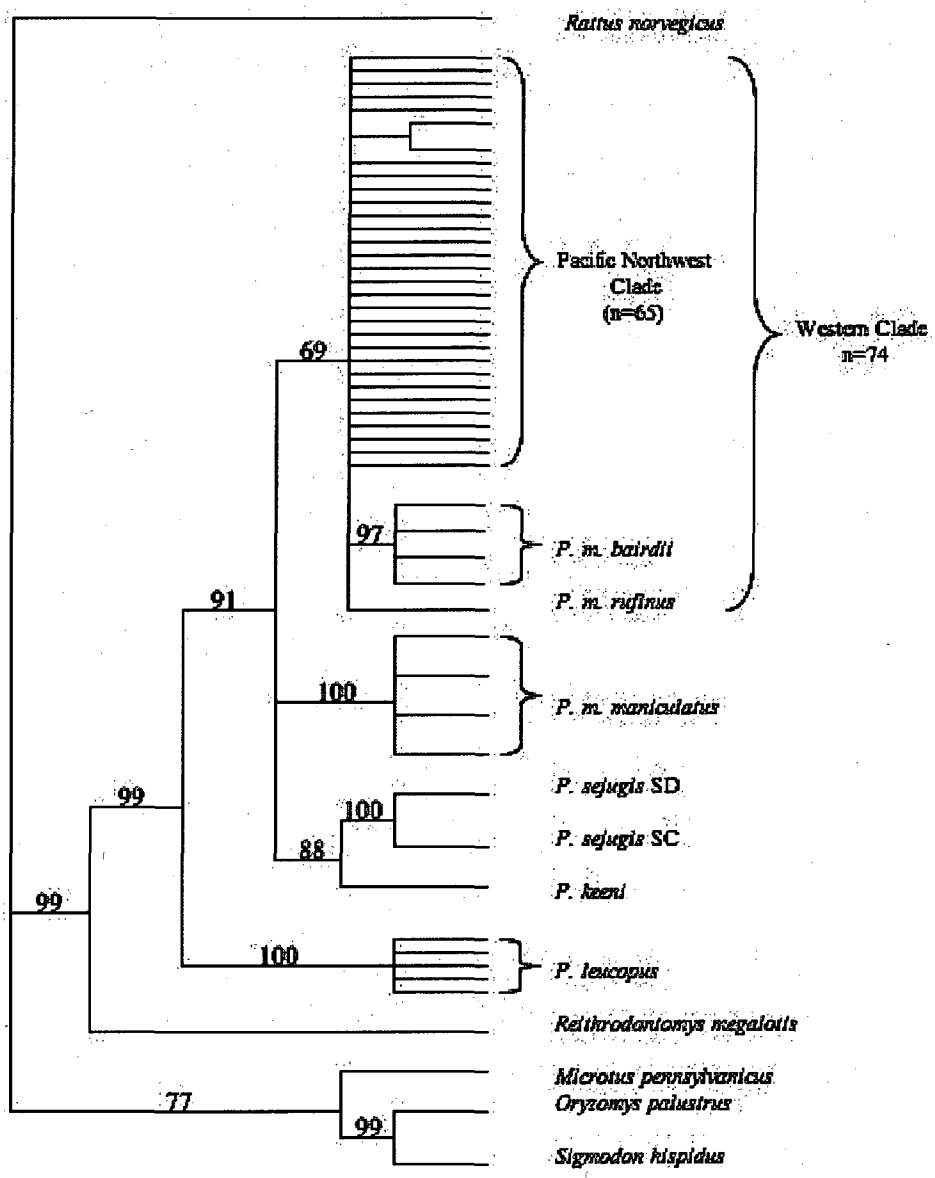

Figure 11: *Peromyscus* Maximum Likelihood Bootstrap Tree. ML tree of *Peromyscus* and outgroups (n=88) using 1,463bp of mitochondrial ND3, ND4, ND4L, and arginine tRNA genes. Numbers represent bootstrap support for nodes after 1000 replicates. –lnL = 8702.95284. Evolutionary model is GTR+I+Γ. SD=San Diego Island. SC=Santa Cruz Island.

Among-site rate variation	
Proportion of invariable sites (I) =	0.2851
Variable sites (G)	
Gamma distribution shape parameter =	0.7693

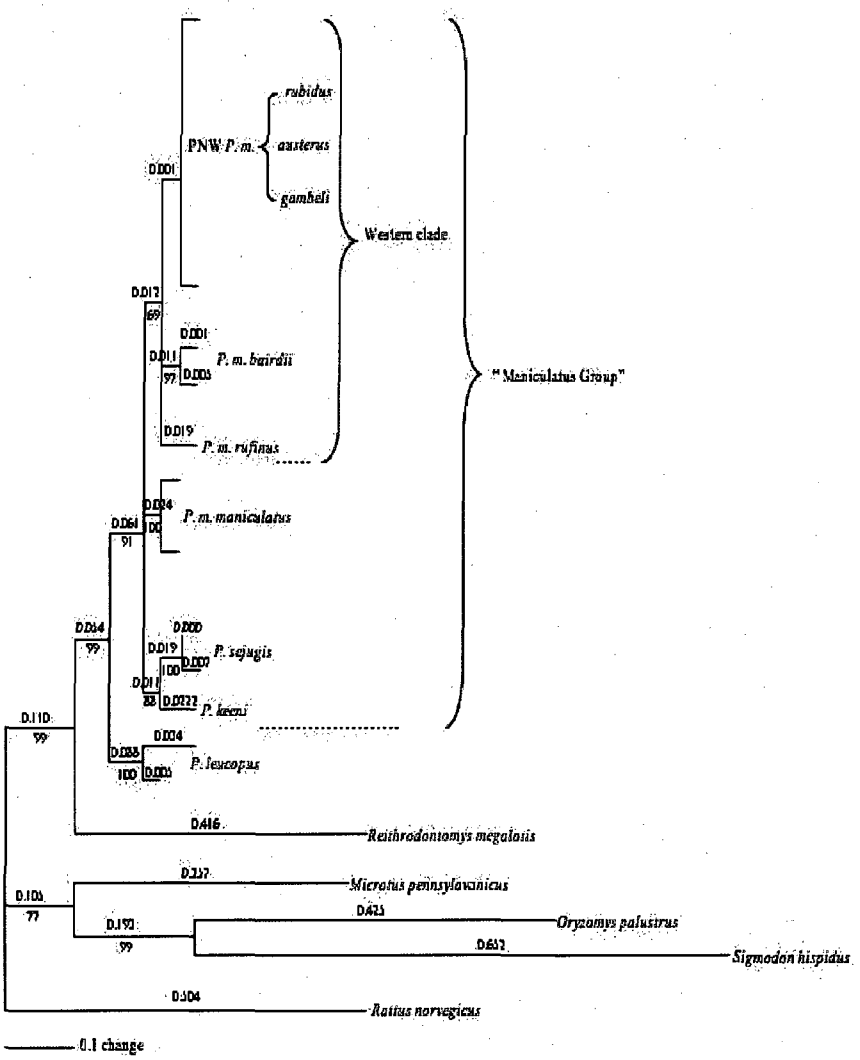

Figure 12: *Peromyscus* Bootstrap/Distance Tree. Combined tree of figures 9 and 10 for direct comparison based upon *Peromyscus* and out-group (n=88) mitochondrial ND3, ND4, ND4L, and arginine tRNA genes (1,463bp). Neighbor-Joining tree (fig. 10) with bootstrap values added from Maximum Likelihood tree (fig. 9) where nodes are identical.

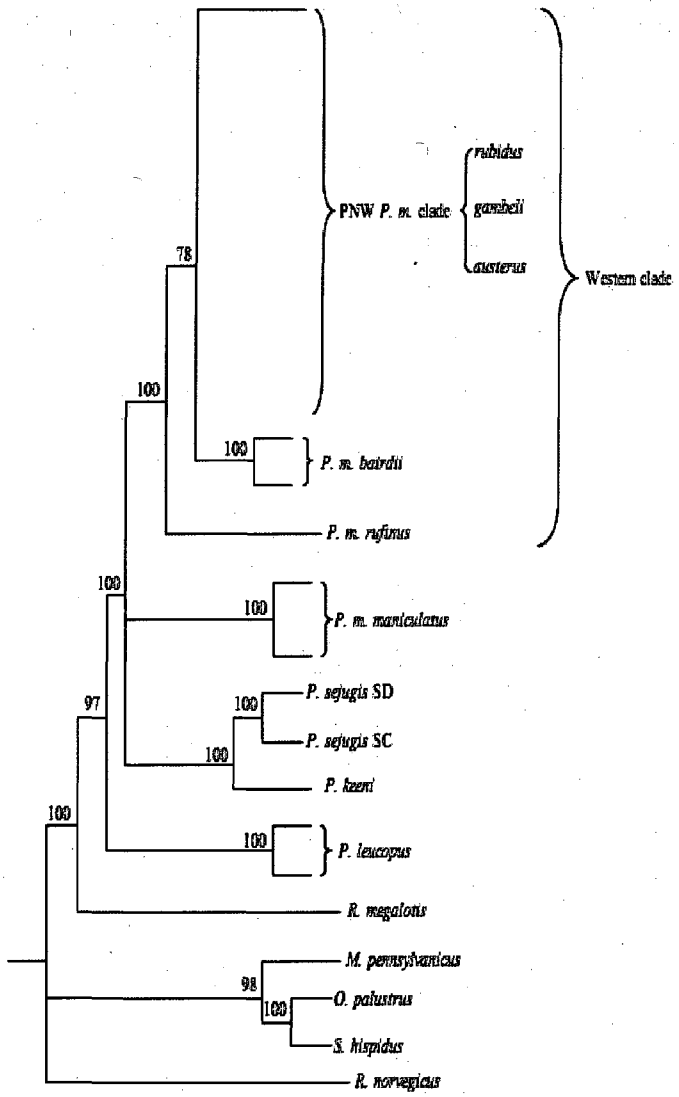

Figure 13: *Peromyscus* Bayesian Majority-Rule Consensus Tree. Based upon *Peromyscus* and outgroups (n=88) mitochondrial ND3, ND4, ND4L, and arginine tRNA genes (1,463bp). Numbers represent bipartition posterior probabilities from 500,000 generations in two runs of four separate Metropolis coupled Markov Chain Monte Carlo computations. Final average standard deviation of split frequencies is 0.0077. Consensus tree derived from majority-rule search of 8,002 sample trees from 800,000 generations.

Component information (consensus fork) = 15 (normalized = 0.652)
Nelson-Platnick term information = 96
Nelson-Platnick total information = 111
Mickevich's consensus information = 0.347
Colless weighted consensus fork (proportion max. information) = 0.371
Schuh-Farris levels sum = 0 (normalized = 0.000)
Rohlf's CI(1) = 0.615
Rohlf's -ln CI(2) = 55.242 (CI(2) = 1.02e-24)

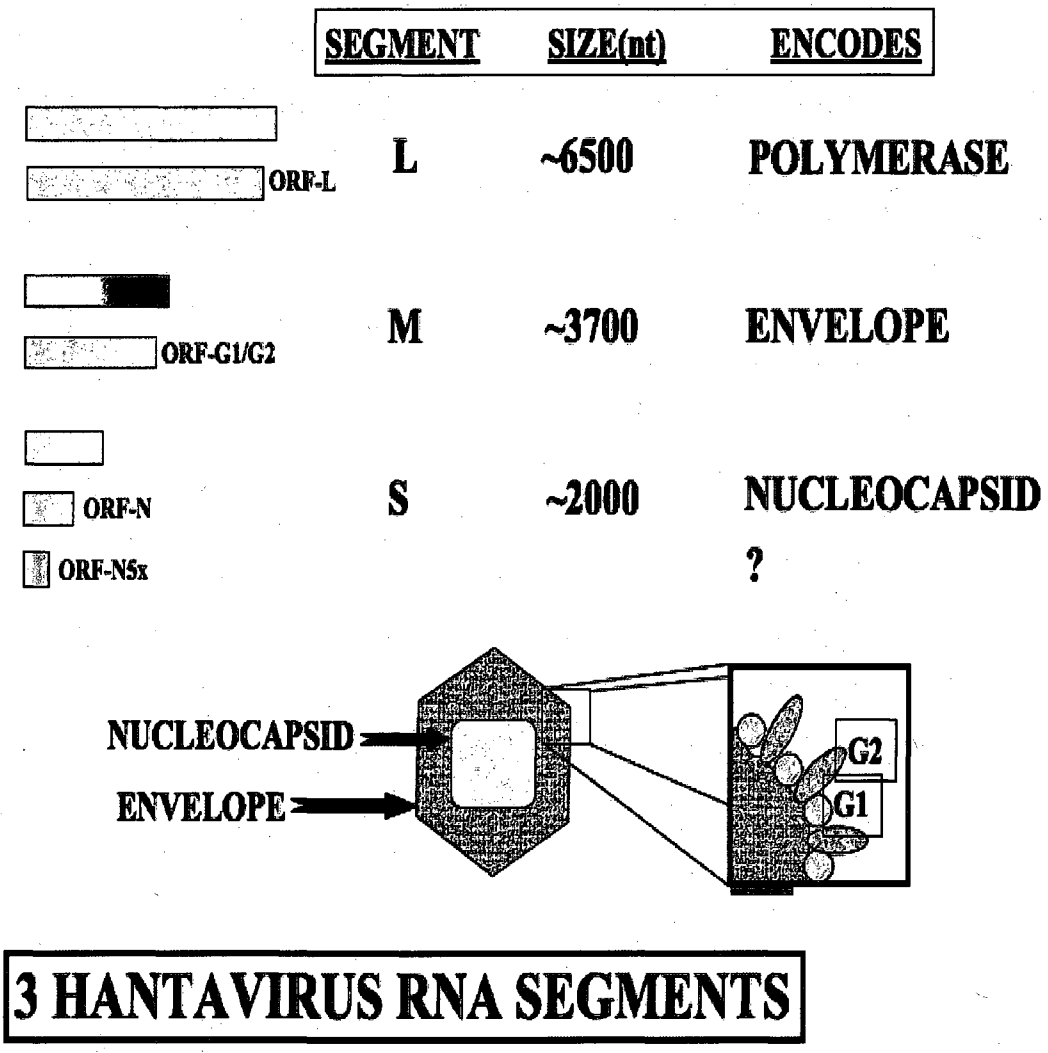

FIGURE 14: ***Hantavirus*** **genome map.** Family Bunyaviridae. Tripartite single-stranded negative sense RNA genome. ~12,200nt total. Targeted G1/G2 glycoprotein precursor gene encoded in M segment.

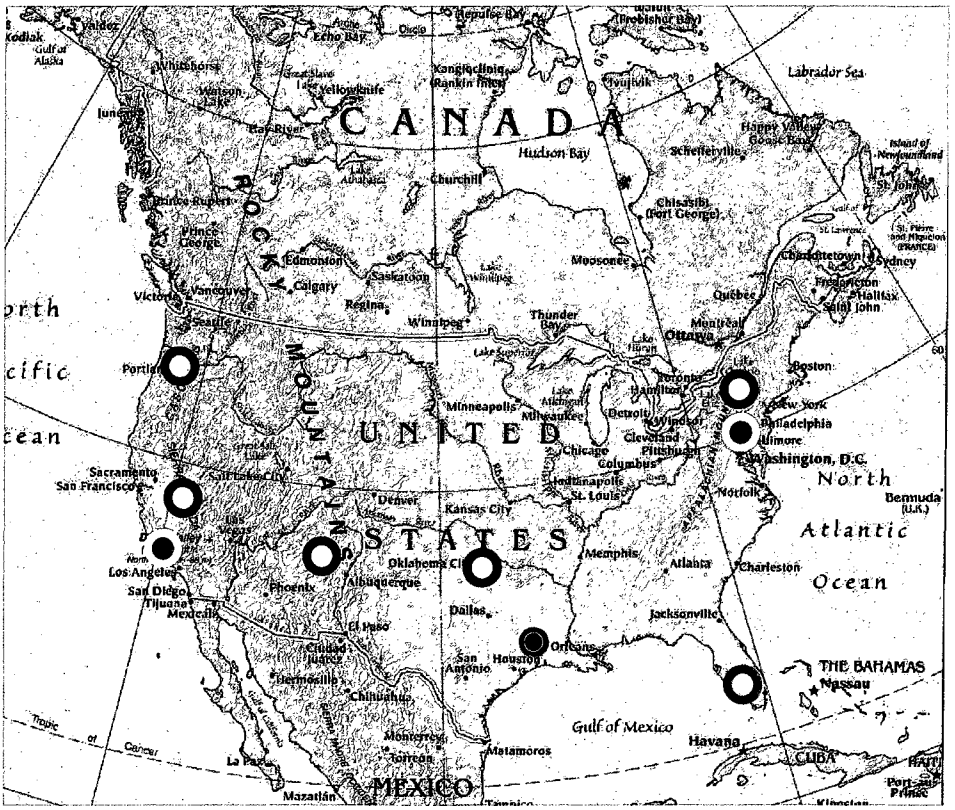

PAIR-WISE QUASI-SPECIES	UNCORRECTED DISTANCE	CORRECTED DISTANCE (GTR+I+Γ)
KV(OR) / CC	0.112	0.158
KV / SNV	0.143	0.251

KV / PH	0.331	1.226
SNV / CC	0.130	0.228
SNV / NY	0.189	0.384
SNV / EMC	0.269	0.662

Figure 15: *Hantavirus* Pair-wise Distances: Pair-wise percent genetic distance among North American hantaviruses (n=44) of G1/G2 glycoprotein precursor gene (617nt). KV=Kalapuya virus; CC=Convict Creek virus; SNV=Sin Nombre virus; NY=New York virus; BR=Blue River virus; BAY=Bayou virus; BCC=Black Creek Canal virus; EMC=El Moro Canyon virus; PH=Prospect Hill virus. Corresponding colored dots represent specimen location. Rodent virus hosts: Yellow dot center=*P. maniculatus*, white=*P. leucopus*, aqua=*S. hispidus*, black=*O. palustrus*, red=*R. megalotis*. Corrected Distance derived with General Time Reversible model of evolution with a proportion of sites invariant and gamma distributed variance, as selected by MODELTEST (Posada and Crandall, 1998).

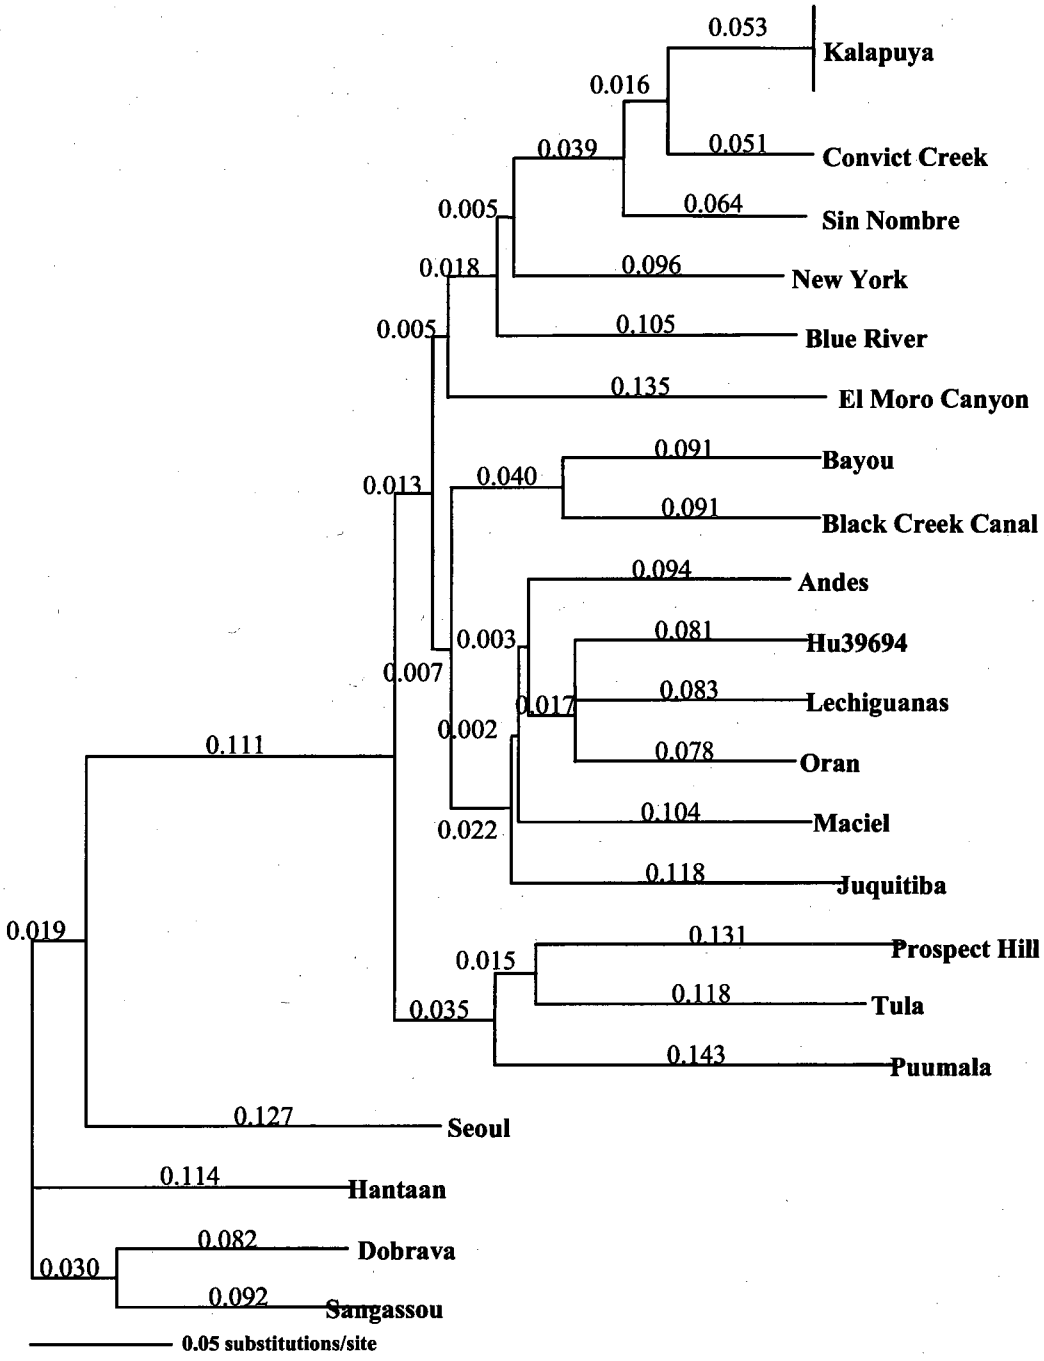

Figure 16: *Hantavirus* Neighbor-Joining Distance Tree. NJ tree of 617nt of *Hantavirus* G1/G2 glycoprotein precursor gene (n=44). Numbers represent branch length as changes from preceding node.

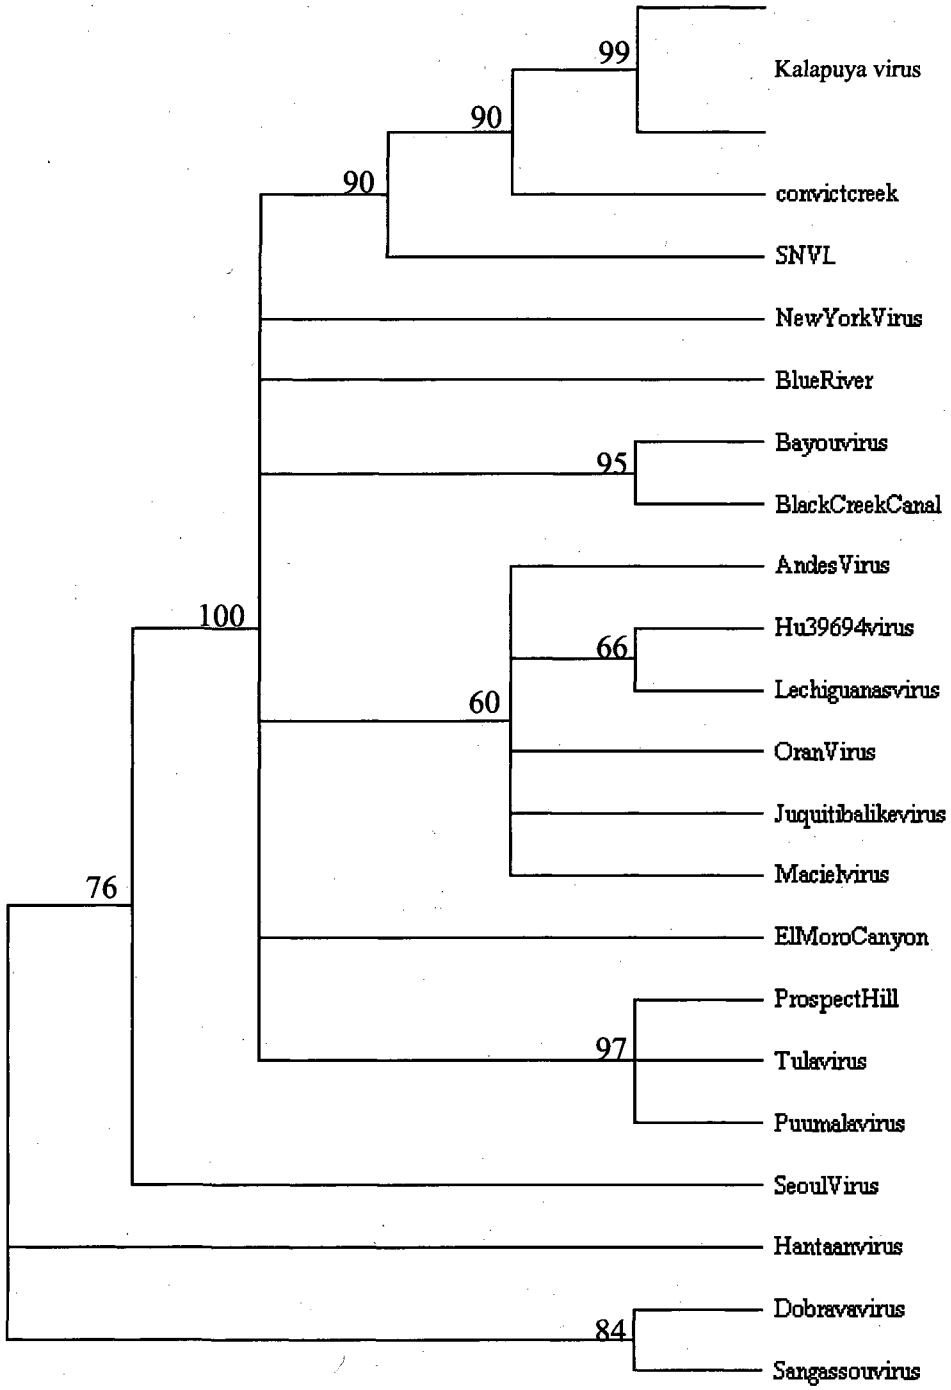

Figure 17: *Hantavirus* Maximum Likelihood Bootstrap Consensus Tree. *Hantavirus* ML tree based upon 617nt of M segment G1/G2 glycoprotein precursor gene (n=44). Numbers represent bootstrap support for nodes after 1000 replicates. Evolutionary model is GTR+I+Γ. –lnL = 8011.8281.

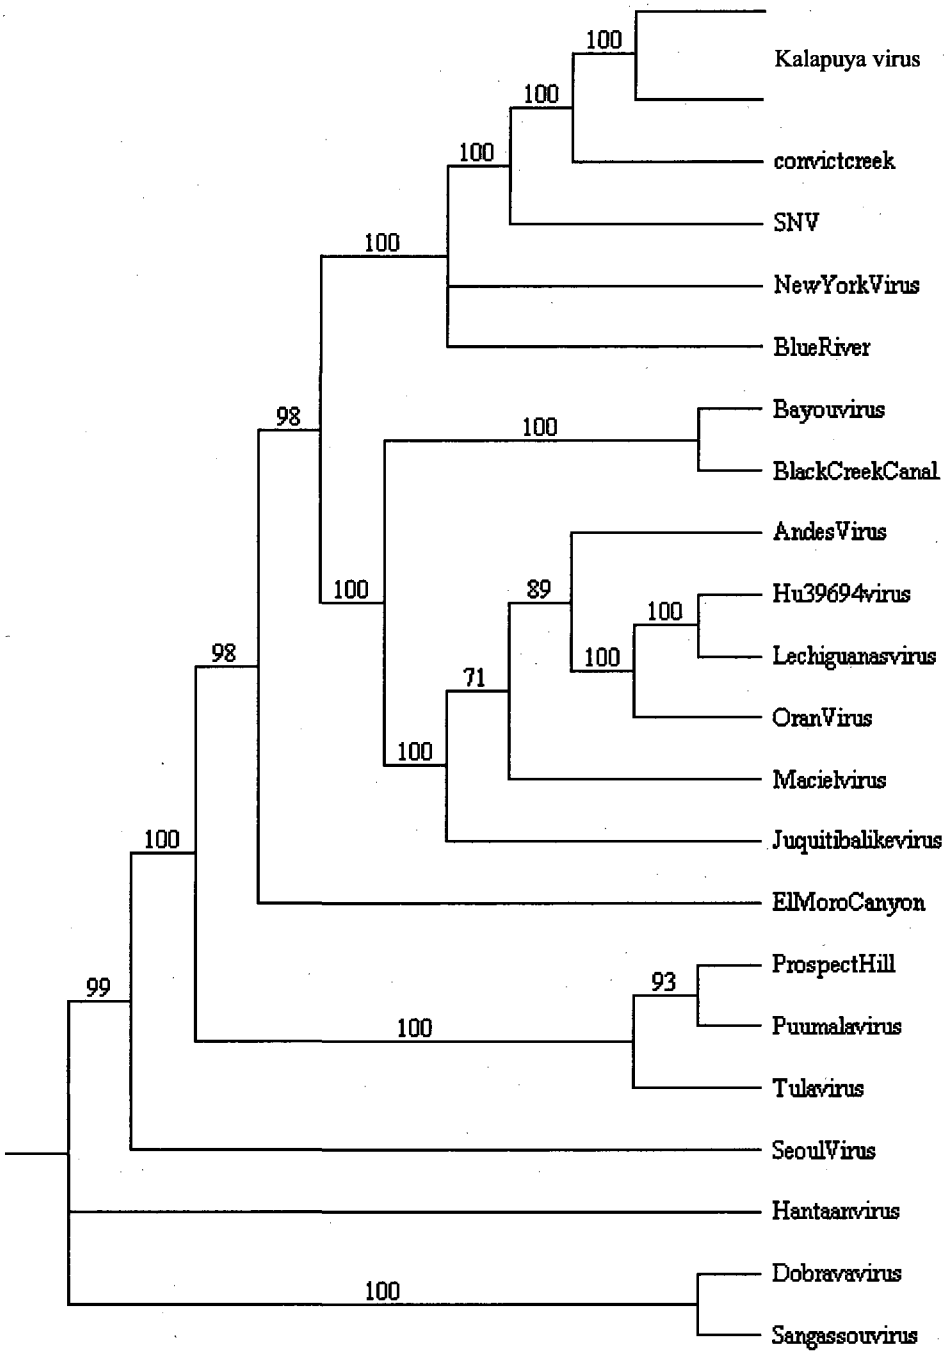

Figure 18: *Hantavirus* Bayesian Majority-Rule Consensus Tree: Tree based upon 617nt of M segment G1/G2 glycoprotein precursor gene (n=44). Numbers represent bipartition posterior probabilities from 500,000 generations in two runs of four separate Metropolis coupled Markov Chain Monte Carlo computations. Final average standard deviation of split frequencies is 0.0023. Consensus tree derived from majority-rule search of 8,002 sample trees from 800,000 generations.

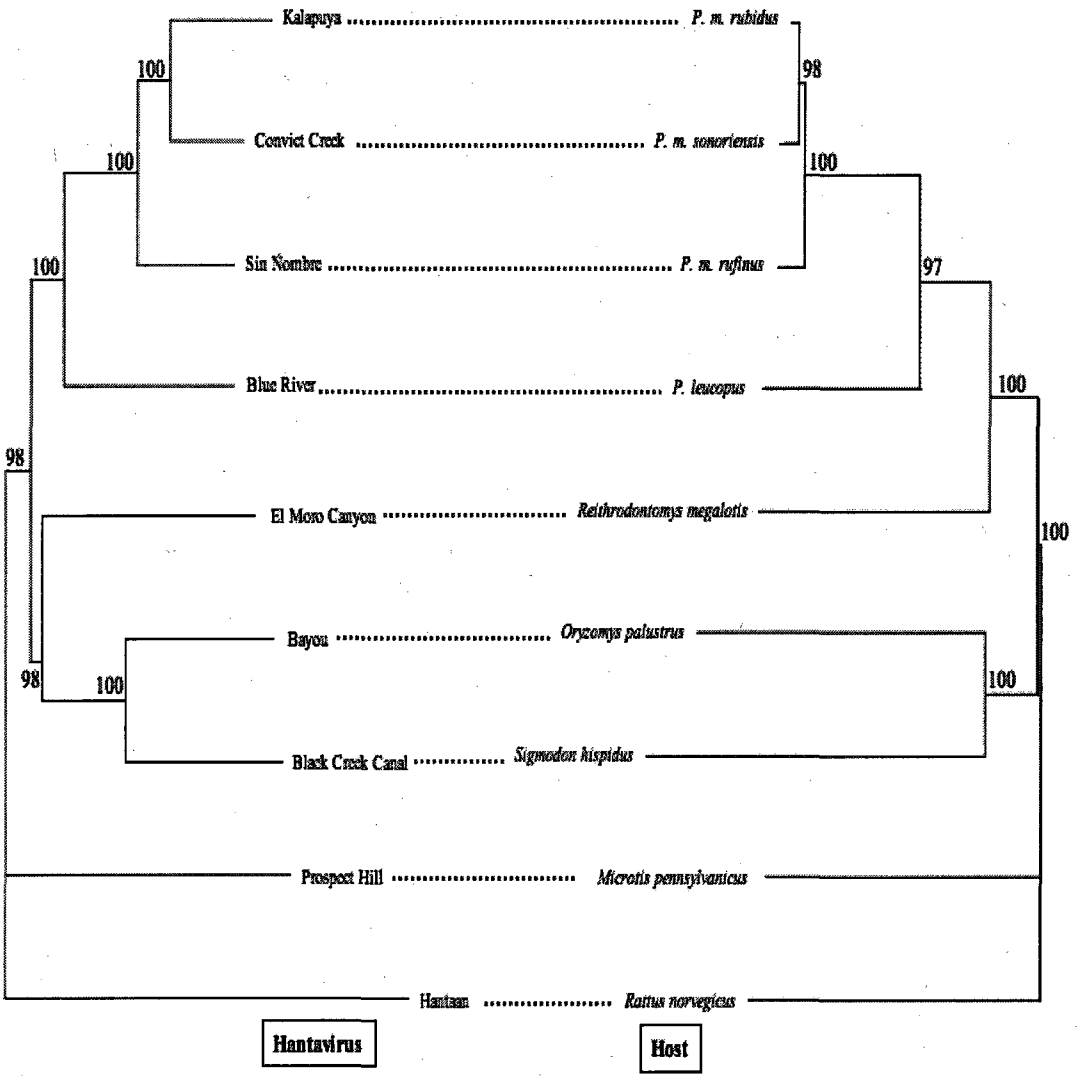

Figure 19: *Hantavirus* / Host Co-Evolutionary Tree. Comparative Bayesian trees of North American hantaviruses (and one Asian) and the rodent hosts for those hantaviruses. *Hantavirus* tree based upon 617nt of M segment G1/G2 glycoprotein precursor gene. Host tree based on 1,463bp of mitochondrial ND3, ND4, ND4L, and arginine tRNA genes. Numbers represent bifurcation posterior probabilities based upon 100,000 generations of Metropolis coupled Markov Chain Monte Carlo computations.

Virus	Disease	Known or suspected host	Location
Cricetidae associated			
Sin Nombre	HPS	*Peromyscus maniculatus* (grassland form)	West & Central U.S. and Canada
Monongahela	HPS	*P. maniculatus* (forest form)	Eastern U.S. and Canada
New York	HPS	*P. leucopus* (eastern haplotype)	Eastern U.S.
Blue River		*P. leucopus* (SW/NW haplotypes)	Central U.S.
Bayou	HPS	*Oryzomys palustris*	Southwestern U.S.
Black Creek Canal	HPS	*Sigmodon hispidus* (eastern form)	Florida
Muleshoe		*S. hispidus* (western form)	Southern U.S.
Caño Delgadito		*S. alstoni*	Venezuela
Andes	HPS	*Oligoryzomys longicaudatus*	Argentina and Chile
Oran	HPS	*O. longicaudatus*	Northwestern Argentina

Appendix C: Specimen Capture Data. Small mammal field captures in the Portland, OR region during the period October, 2002 through October, 2005.

PM = *Peromyscus maniculatus*
ST = *Sorex trowbridgii*
SV = *Sorex vagrans*
NG = *Neurotrichus gibsii*
MO = *Microtis oregoni*
SB = *Sorex bendirii*
PL = *Procyon lotor*
MT = *Microtus townsendii*
SN = *Sciurus niger*
TD = *Tamiasciurus douglasii*
TT = *Tamias townsendii*
ST = *Scapanus townsendii*
DV = *Didelphis virginianus*
MM = *Mephitis mephitis*
ME = *Mustela erminea*
SG = *Spilogale gracilis*

Appendix D: *Hantavirus* Antibody-Positive Specimens. Small mammals found infected with *Hantavirus* during the period October, 2002 through October, 2005. The positive *Glaucomys sabrinus* (likely due to a spill-over event) was unable to be confirmed after release of the specimen.

Appendix H: Hantavirus Multiple Sequence Alignment. Sequences of M segment G1/G2 glycoprotein precursor gene aligned with one another and adjusted to codon reading frame. T*=Troutdale, WC=Washington County, WCps=Washington County patient sample, LJD*=Portland area specimens collected for this research.
